The study of the properties of this remarkable substance enables us to gain a clearer insight into the nature of the chemical process attending the glow of phosphorus. When phosphorus is placed in oxygen, or in an atmosphere containing oxygen, under such conditions that it volatilizes, the phosphorus oxidizes, partly into phosphoric oxide and partly into phosphorous oxide. Ozone is formed, possibly by the reaction already indicated, and this reacts upon the residual phosphorus vapour and the phosphorous oxide with the production of the luminous effect to which the element owes its name. The glow itself is nothing but a slowly-burning flame having an extremely low temperature, caused by the chemical union of oxygen with the vapours of phosphorus and phosphorous oxide. By suitable means this glow can be gradually augmented, until it passes by regular gradation into the active vigorous combustion which we ordinarily associate with flame. Many substances, in fact, may be caused to phosphoresce in a similar way. Arsenic, when gently heated, glows in oxygen, and sulphur may also be observed to become luminous in that gas at a temperature of about 200°.

"BEFORE AND AFTER DARWIN."

ON Tuesday, March 25, Prof. G. J. Romanes, F.R.S., concluded his course of between thirty and forty lectures, which, under the above title, he has been delivering at the Royal Institution during the last three years. At the close of the lecture he announced his intention of publishing the whole course in November next, and distributed among the audience printed slips, conveying in the form of twelve propositions the "general conclusions" to which his lectures for the present year have led. The following is a copy of this printed slip:—

(1) "Natural selection has been the main, but not the exclusive means of modification," both as regards species and all the higher taxonomic divisions.

(2) Of the other factors of organic evolution it is not improbable that we are still to a large extent ignorant. Whether, or to what extent, sexual selection and the Lamarckian principles have co-operated, is a matter with which I am not specially concerned; but I think there is abundant evidence to establish the high importance in this connection of amixia, or independent variability,—at all events as regards the evolution of species.

(3) Natural selection is primarily a theory of the cumulative development of adaptations wherever these occur, and therefore is only incidentally, or likewise, a theory of the origin of species in cases where allied species differ from one another in respect of peculiar characters, which are also adaptive characters.

(4) Hence it does not follow from the theory of natural selection that all species—much less all specific characters—must *necessarily* have owed their origin to natural selection, since it cannot be proved deductively from the theory that no "means of modification" other than natural selection is competent to produce such slight degrees of modification as go to constitute diagnostic distinctions between closely-allied species: while, on the other hand, there is an overwhelming mass of evidence to prove the origin of "a large proportional number of specific characters" in causes of modification other than natural selection.

(5) Even if it were true that all species and all specific characters must necessarily owe their origin to natural selection, it would still remain illogical to define the theory of natural selection as indifferently a theory of species or a theory of adaptations; for, even upon this erroneous supposition, specific characters and adaptive characters would remain very far indeed from being conterminous—by far the larger number of adaptations which occur in organic nature being the common property of many species.

(6) In no case can natural selection have been the cause of mutual infertility between allied or any other species.

(7) Without isolation, in the sense of either separate or segregate breeding, organic evolution is in no case possible; and hence, heredity and variability being given, the whole theory of organic evolution may be regarded as a theory of the causes and conditions which have led to isolation, or the mating of similar variations to the exclusion of dissimilar.

(8) Natural selection is one among sundry distinct kinds of isolation, and presents in this relation the following peculiarities: (*a*) the isolation is with reference to superiority of fitness; (*b*) is effected by destruction of the excluded individuals; and (*c*) unless assisted by some other kind of isolation, can only effect monotypic as distinguished from polytypic evolution.

(9) It is a general law of organic evolution that the number of possible directions in which divergence may occur can never be more than equal to the number of cases of efficient isolation; but, excepting natural selection, any one kind of isolation need not necessarily require the co-operation of another kind in order to create an additional case of isolation, or to cause polytypic as distinguished from monotypic evolution.

(10) Where common areas are concerned, the most general and most efficient kind of isolation has been the physiological—and this whether the mutual infertility has been the antecedent or the consequent of morphological changes on the part of the types concerned, and whether or not these changes are of an adaptive character.

(11) This form of isolation—which in regard to *incipient species* I have called physiological selection—may act either alone, or in conjunction with other kinds of isolation on common areas: in the former case its agency is of most importance among plants and the lower classes of animals; in the latter case its importance consists in its greatly intensifying the segregating power of whatever other kind of isolation it may be with which it is associated.

(12) Although physiological selection must in all cases refer primarily to first crosses, its activity as a cause of segregation is intensified in cases where it extends also to second crosses.

SCIENTIFIC SERIALS.

American Journal of Mathematics, vol. xii., No. 3 (Baltimore, March 1890.)—A memoir "Sur les équations aux dérivées partielles de la physique mathématique," by that brilliant mathematician, M. Poincaré, occupies pp. 211–294. Some idea of the writer's aim will be gained from the following passages:—"Quand on envisage les divers problèmes de calcul intégral qui se posent naturellement lorsqu'on veut approfondir les parties les plus différentes de la physique, il est impossible de n'être pas frappé des analogies que tous ces problèmes présentent entre eux." "Cette revue rapide des diverses parties de la physique mathématique nous a convaincus que tous ces problèmes, malgré l'extrême variété des conditions aux limites, et même des équations différentielles, ont, pour ainsi dire, un certain air de famille qu'il est impossible de méconnaître. On doit donc s'attendre à leur trouver un très grand nombre de propriétés communes." The concluding sentence is: "Je pourrai dire alors que les conclusions sont démontrées d'une façon rigoureuse au point de vue physique. Peut être même est-il permis d'espérer que, par une sorte de passage à la limite, on pourra fonder sur ces principes une démonstration rigoureuse même au point de vue analytique."—The remaining article of the number is one on singular solutions of ordinary differential equations, by H. B. Fine (pp. 295–322). Following the lead of Briot and Bouquet, this memoir bases the theory of singular solutions on the differential equation, and avoids all use, direct or indirect, of the notion of the complete primitive.

In *Bulletin* No. 2 of the Brussels Academy of Science, M. E. Ronkar criticizes a paper by M. J. Liagre, on the mutual impulse of the earth's surface and centre because of interior friction. The paper in question dealt with the interior structure of the earth, and the conclusions drawn have some bearing on diurnal nutation.—In a paper on the venous pulse, M. Léon Fredericq gives his investigations into the form of various pulses—jugular, venous, and carotid; traces the identity of the pulse of the jugular vein and that of the right auricle; and discusses generally the phenomena of circulation and respiration. The same author adds a note on the preservation of oxyhæmoglobin.—M. A. F. Renard has examined phillipsite crystals from the deposits obtained from the centre of the Pacific Ocean. These microscopical crystals were discovered by Mr. Murray, and a brief description of them published by him in conjunction with the author in 1884 (Royal Society of Edinburgh). A more particular description and determination of the character of these zeolites, and the deposits in which they occur, is now given. A plate containing four drawings of the crystals accompanies the paper.—M. G. van der Mensbrugghe, in a paper on the condensation of water-vapour in capillary spaces, reviews the principal facts owing their origin to such condensation, and shows that they are in confirmation of the theory propounded by Sir William Thomson in 1874, in a paper on the equilibrium of vapour at a curved surface of liquid. The experimental verification of the formula there given will form the subject of a second communication.

SOCIETIES AND ACADEMIES.

London.

Royal Society, February 20.—"Some Stages in the Development of the Brain of *Clupea harengus*." By Ernest W. L. Holt, Marine Laboratory, St. Andrews. Communicated by Prof. McIntosh, F.R.S.

The stages described are (i) newly-hatched or early larval; (ii) early post-larval; (iii) ½ inch long; (iv) ¾ inch long.

The development of the pineal region is treated separately, and in this a fifth stage—1 1/12 inch long—is introduced.

In the early larval stage the downward flexure of the fore part of the brain is very noticeable. It appears due to the general conformation of the head at this stage. A diverticulum of the 3rd ventricle extends downwards and backwards, its distal extremity underlying the optic commissure. The broad ventral commissure of the infundibulum, noticed by McIntosh and Prince in *Anarrhicas*, is well marked. A commissure shuts off the lumen of the infundibulum from the hind part of the 3rd ventricle immediately in front of the splitting off of the infundibulum. The valvula appears in transverse section as a pair of ridges externally to the tori, before it shuts off the aqueduct of Sylvius. The cerebellar fold is very short.

In the early post-larval stage "an apparent rectification of the cranial axis" has taken place, by the upward rotation of the cerebrum on its posterior end, doubtless owing to the rapid development of the oral and trabecular cartilages, and consequent forward rotation of the mouth. The same causes have also operated so as to withdraw the diverticulum of the 3rd ventricle from its position below the optic commissure. The infundibulum has undergone vertical flattening. The future lobi inferiores are indicated as lateral expansions, behind which the 3rd oculomotor nerves pass outwards from the centre of the ventral surface of the cerebral mass. The infundibulum extends some way back above the notochord as a thin-walled sac. Its walls are little plicated compared with those in some other forms, *e.g.*, *Rhombus*, *Anarrhicas*.

In the ½-inch stage the olfactory lobes appear as bulbous masses projecting from the front end of the cerebrum. A pale median septum appears between the anterior extremities of the lateral optic ventricles, its base resting on the fibrous tract over the hind part of the 3rd ventricle. The tip of the valvula now appears in transverse section before its connection with the cerebral mass can be made out, having thus grown forward. The cerebellum has greatly increased in size; instead of terminating as before on the surface of the brain, it is now continued into a thick fold bent sharply down on the anterior portion; its posterior end passes at once into the thin roof of the 4th ventricle. Two fibrous bands cross over the aqueduct of Sylvius in the substance of the cerebellum; their lateral extremities are fused. The lobi inferiores are better marked than in earlier stages. Longitudinal bands of fibres pass back from the roots of the oculomotor nerves through the medulla oblongata. Groups of large ganglionic cells appear on either side of these bands, and are connected by a fine commissure passing through both bands. At the origin of the 8th auditory nerves, this commissure is replaced by a St. Andrew's cross of fibres, the dorsal limbs of the cross passing to the nerve roots, and the ventral to the ganglionic areas.

In the ¾-inch stage the olfactory lobes are more elongated. The olfactory nerves pass outwards from their anterior extremities. The septum behind the pineal body, after losing its ventral connection with the fibrous tract over the 3rd ventricle, persists for some way back as a cellular leaf-like appendage of the thin median roof of the optic ventricle; a few fibres pass back into this appendage.

Large ganglionic cells appear in the tori semicirculares about the region of the splitting off of the infundibulum.

From behind the region of the auditory nerves a ganglionic area on either side persists backwards through the medulla oblongata.

Pineal Region.

The roof of the thalamencephalon in the early stages is a single layer of large columnar cells passing forward from the front wall of the pineal stalk. It passes into the roof of the cerebrum, the cells diminishing greatly in size. The superior commissure of Osborn is present from the early post-larval stage; it it also present in the larval and post-larval *Zoarces viviparus*, where it is distinctly double. The first signs of the infrapineal recess of Hoffman are seen in the ½-inch stage. It is thus much later in developing than in *Salmo*, and the fold forming its front wall never extends backwards to the same degree as in that form and in *Anarrhicas*. This fold, in the post-larval *Zoarces*, is thickened in its apex, and lodges a fine commissure. As pointed out by Balfour in Elasmobranchs the fold is due to the upward rotation of the cerebrum.

The fibrous tract over the 3rd ventricle in the herring is well marked in the ¾-inch stage. It is seen to consist of fibres passing upwards and inwards from the optic thalami to the middle line above the 3rd ventricle, and then running forward to the stalk of the pineal body. The tract has a double nature, as is readily seen in vertical longitudinal sections of a herring 1 1/12 inch long. It is seen here to be a backwardly directed fold of the brain roof, continuous ventrally with the back wall of the pineal stalk, and dorsally with the roof of the optic ventricle, the apex of the fold being the posterior commissure. Its length in this form is due to the flattening of the brain, the tract being very short in

Zoarces, where the brain is not flattened. In *Zoarces*, also, from the same cause, the limbs of the fold are less closely applied to each other and much thicker.

The pineal body is roundish and solid in the early larval stage in the herring. It is vertically flattened in the early post-larval stage. In the ½-inch stage it is much larger and contains a lumen; it shows signs of constriction into proximal and distal elements, and the lumen contains a coagulable albuminous fluid, as in *Petromyzon*. In the $1\frac{1}{12}$-inch stage the constriction is still visible, and the walls are generally crenated. The tissues of the pineal wall are now divided into three layers, and are of varying thickness. The cartilage of the tegumen cranii overlies the body at this stage. The constriction of the body appears to be an exaggeration of the crenation of the pineal wall met with in *Salmo*; it has not, probably, the morphological value of the constriction of the body in *Petromyzon*.

March 27.—"On the Stability of a Rotating Spheroid of Perfect Liquid." By G. H. Bryan. Communicated by Prof. G. H. Darwin.

The investigations of Riemann, Basset, and others have proved that Maclaurin's spheroid, when composed of frictionless liquid, ceases to be stable for an "ellipsoidal" type of disturbance when its eccentricity attains the value 0·952886-. The object of the present paper is to discuss the conditions of stability with reference to disturbances of a general type expressible in terms of spheroidal harmonics, with the view of examining whether Riemann's condition is sufficient to ensure stability for displacements other than ellipsoidal.

Taking the criteria of stability determined in a previous communication (Phil. Trans., A., 1889), the author shows by numerical calculation that the form which is critical for an ellipsoidal disturbance is stable for disturbances determined by several of the lower harmonics. These results are then extended by a perfectly general investigation to all other types of displacement.

The conclusion is that Riemann's and Basset's condition of stability is sufficient to ensure the absolute stability of Maclaurin's rotating spheroid for every possible displacement. Also that, unless the liquid is subject to hypothetical constraints, we cannot initially obtain any form other than ellipsoidal from the instability of the spheroidal form. In the case considered of perfect liquid this ellipsoid does not rotate as if rigid, but its principal axes rotate with half the angular velocity of the liquid.

Physical Society, March 7.—Prof. W. E. Ayrton, F.R.S., President, in the chair.—Dr. S. P. Thompson described Bertrand's refractometer, and exhibited the capabilities of the instrument before the Society. Its action depends on total reflection. The refractometer consists of a hemisphere of glass, about 8 mm. diameter, set at the end of a tube, the plane face being outwards and inclined at about 30° with the axis. One side of the convex surface of the hemisphere is illuminated through a piece of ground glass set about perpendicular to the plane face. The hemisphere is viewed through an eye-piece focussed on a scale divided to tenths of millimetres placed within the tube. The instrument is particularly useful for mineralogical specimens and liquids. The procedure in the latter case is to smear a film of the liquid over the plane face of the hemisphere, and by looking through the eye-piece determine the scale reading of the line which separates the light and darker portions of the field. A reference to a calibration table gives the refractive index. In experimenting with solids a thin film of a very dense liquid (supplied with the instrument) is placed between the specimen and the glass, and the procedure is then as above. The refractive index of opaque solids can be determined in this way. In using the instrument for minerals great care must be taken not to scratch the glass. The handiness of the refractometer and its perfect portability (its dimensions being about 5 centimetres long by 2½ cm. diameter) are great recommendations. Mr. Blakesley asked to what accuracy the scale could be read, and whether the sensitiveness of the instrument was at all comparable with that of other methods. Prof. Dunstan inquired if it could be used with volatile liquids. In reply Dr. Thompson said that with non-homogeneous light the scale could be read to 1 division, but with a sodium flame one-tenth of a division could be estimated. For volatile liquids, a drop may be used instead of a film, or the evaporation of a thick film may be retarded by a cover-glass.—Mr. H. Tomlinson's paper, on the Villari critical point in nickel, was postponed.—Prof. Dunstan described an apparatus for distilling mercury in a vacuum, devised by himself and W. Dymond, and showed the working of the arrangement. It consists of a 3 mm. soft glass tube rather more than a metre long, having an oblate spheroidal bulb blown at the upper end. The bulb is placed over a ring burner. At the top of the bulb, a tube of 1·5 mm. diameter is attached, and this passes outside the bulb, and descends close to the larger tube. The part of the smaller or fall tube just below the bulb is enlarged so as to form a condensation chamber, and the lower part serves as a Sprengel tube. A conical reservoir containing the mercury to be distilled is in flexible connection with the lower end of the large tube as in Clark's well-known apparatus. The advantages claimed for the new apparatus are, its relative shortness and portability, the small quantity remaining undistilled, and its non-liability to damage or derangement if left unsupplied with mercury. To ensure satisfactory working a constant pressure of gas is necessary, and this is obtained by inserting a Sugg's dry governor in the supply pipe. During distillation, peculiar green flashes are seen within the condensation chamber, and these are intensified by bringing it near an electric machine in action. The apparatus also serves well to show the character of an electric discharge through mercury vapour, for the mercury in the two tubes may be used as electrodes. Prof. Thompson said he devised a simple form of distilling apparatus some time ago which answered fairly well, and could be made by any amateur glass-worker. It consisted of a double barometer, one leg of which was of small bore, so as to act as a Sprengel tube. The rising part of the bend at the top of the larger tube was expanded and served as the evaporating chamber, below which a burner was placed. The President asked why Clark's apparatus is made so lengthy. In reply to this question Mr. Boys said that as the fall tube goes down within the rising one, the mercury near the top of the latter is heated by the condensing mercury (thus economising gas) and hence condensation does not take place until the vapour has passed a considerable distance down the fall tube.—Prof. S. U. Pickering read a paper on the theory of osmotic pressure and its bearing on the nature of solution. The author said that considerable doubt exists as to the accuracy of the premises on which the theory is based, and if the theory is to be regarded as true and not merely a rough working hypothesis, the following conditions must be fulfilled by weak solutions—(1) The molecular depression of the freezing-point must be independent of the nature of the dissolved substance. (2) Any deviations from (1) must be in the direction indicated by the theory. (3) the depression must be independent of the nature of solvent. (4) The depression must be independent of the amount of solvent (all solutions being weak). (5) The deviations with strong solutions should be in the theoretical direction. (6) They should be regular. Prof. Pickering proceeded to show that experiment, instead of confirming the above statements, disproves them all. As regards (1), without counting abnormally low (half) values, Raoult's results show variations of 60, 40, 30, &c., per cent. in different cases, and the author quoted other values where the variations were 500, 260, 230, &c., per cent. These variations, he considered, were too great to be explained by the fact of the solutions used being 3 or 4 times too strong. Referring to (2), he said that low values are reasonably explained by the polymerization of the dissolved molecules, high values by their dissociation into ions. He then argued that there are no abnormally high values, for the view that such exist, and that they are explainable by dissociation involves the following conclusions: (*a*) that the more stable a substance is, the more easily is it dissociated; (*b*) that solution dissociates molecules which we know can exist undissociated as gases; (*c*) that water must consist of $1\frac{1}{2}H_2O$, and the atomic theory is wrong; (*d*) that energy can be created, and therefore the theory of its conservation is untenable. With respect to (3), it was pointed out that in many instances the same dissolved substance gives the full depression with one solvent and half depression with another. Cases were quoted where the depression produced by the same dissolved body in different solvents showed variations of 36,000, 21,000, and 28,000 per cent. In discussing (4), the author said that even with solutions weaker than that corresponding to a gas, the law is not fulfilled. Taking the case of sulphuric acid (the only one at present fully investigated), the variations amount to 40 per cent., or about 28 times the experimental error. With reference to (5), it was stated that with strong solutions the molecular depression should become smaller, but in every known case (9 were quoted) it becomes larger, the increase in one instance being 3,200 per

cent. As regards (6), all experimental data available, especially those relating to sulphuric acid, show that the deviations are neither regular nor always in the same direction. Mr. T. H. Blakesley said he was greatly interested with Prof. Pickering's paper, for some time ago he was induced to make experiments on the volume of salts in solution by reading Joule's papers on that subject. Some of the results confirmed, but others did not agree with, Joule's theory that the molecular volume in solution was a whole number. If this theory was true, then (he said) it would be possible to predetermine the density of solutions, and from the measured density of any known solution we could determine the water of crystallization of the salt from the formula

$$n = \frac{1 - \frac{W}{w}(D - 1)}{D}\left(\frac{A}{H_2O} + x\right);$$

where W and w are the masses of the water and salt respectively, D the density of the solution relative to water at the same temperature, A the molecular weight of the dehydrated portion of the salt, x the number of molecules of water, and n the molecular volume of the salt in solution, the two latter being whole numbers.

Chemical Society, March 6.—Dr. W. J. Russell, President in the chair.—The President announced that the senior Secretary would attend the meeting to be held in Berlin on March 11 to celebrate the 25th anniversary of the promulgation of Prof. Kekulé's benzene theory, and would present a congratulatory address from the Society.—The following papers were read:—Some crystalline substances obtained from the fruits of various species of *Citrus*, by Prof. W. A. Tilden, F.R.S., and Mr. C. R. Beck. The authors have examined the solid matters which are deposited from freshly extracted oils of limes, lemons, and bergamot made by hand. The substance, limettin, obtained from oil of limes (*C. limetta*) has the composition $C_{16}H_{14}O_6$, and crystallizes in tufts of needles melting at 121°–132°. It is neither an acid nor a glucoside, is not acted upon by acetic chloride or phenylhydrazine, and yields phloroglucol, and acetic and formic acids on fusion with potash. Essence of lemons yields a substance, $C_{14}H_{14}O_6$, very similar to limettin in appearance, though the crystals are more lustrous and melt at 116°. Bergamot yields a compound which crystallizes in colourless prisms and melts at 270°–271°.—Reduction of α-diketones, by Prof. F. R. Japp, F.R.S., and Dr. F. Klingemann. Benzil, when reduced by boiling with fuming hydriodic acid for a few minutes, gives an excellent yield of deoxybenzoïn. Phenanthraquinone, under like conditions, gives so-called phenanthrone, which, contrary to Lachowicz's view, is not the deoxybenzoïn of phenanthraquinone, but a mono-hydroxyphenanthrene.—Studies on isomeric change, No. IV; halogen derivatives of quinone, by Mr. A. R. Ling. The experiments of Hantzsch and Nietzki have proved, in opposition to those of Levy, that the "anilic" acids are paradihydroxy-derivatives of quinone, and Hantzsch and Schniter have shown that an isomeric change occurs when paradichloroquinone is brominated, the product being metadichlorometadibromoquinone. The author has investigated the action of bromine on paradichloroquinone and diacetylparadichloroquinol, and the action of chlorine on paradibromoquinone, and has obtained results which confirm Hantzsch and Schniter's conclusion, since all attempts to prepare paradichloroparadibromoquinone, $CO\langle{}^{CBr.CCl}_{CCl.CBr}\rangle CO$, have been unsuccessful, the product in every case consisting of the isomeric metadichlorometadibromoquinone, $CO\langle{}^{CCl.CBr}_{CCl.CBr}\rangle CO$.—Note on a phenylic salt of phenylthiocarbamic acid, by Prof. A. E. Dixon.—Contributions to the chemistry of thiocarbamides; interaction of benzyl chloride and of allyl bromide with thiocarbamide, phenyl- and diphenylthiocarbamides, by Mr. E. A. Werner.

Geological Society, March 12.—Mr. J. W. Hulke, F.R.S., Vice-President, in the chair.—The following communications were read:—On a deep channel of drift in the valley of the Cam, Essex, by W. Whitaker. In Scotland and in Northern England long and deep channels filled with drift have been noticed, but not in Southern England. For some years one deep well-section has been known which showed a most unexpected thickness of Glacial drift in the higher part of the valley of the Cam, where that drift occurs mostly on the higher grounds and is of no very great thickness. Lately, further evidence has come to hand, showing that the occurrence in question is not confined to one spot, but extends for some miles. The beds found are for the most part loamy or clayey. At the head of the valley various wells at Quendon and Rickling show irregularities in the thickness of the drift, the chalk coming to or near the surface in some places, whilst it is nearly 100 feet below it sometimes. Further north, at Newport, we have the greatest thickness of drift hitherto recorded in the South of England, and then without reaching the base. At one spot a well reached chalk at 75 feet; whilst about 150 feet off that rock crops out, showing a slope of the chalk-surface of 1 in 2. In the most interesting of all the wells, after boring to the depth of 340 feet, the work was abandoned without reaching the chalk, the drift in this case reaching to a depth of about 140 feet below the level of the sea, though the place is far inland. The chalk crops out about 1000 feet eastward, and at but little lower level, so that there is a fall of about 1 in 3 over a long distance. At and near Wenden the abrupt way in which drift comes on against chalk has been seen in open sections. Two wells have shown a thickness of 210 and 296 feet of drift respectively; and as the chalk comes to the surface, at a level certainly not lower, only 140 yards from the latter, the chalk surface must have a slope of 1 in less than 1½, and this surface must rise again on the other side, as the chalk again crops out. The drift here reaches to a depth of 60 or 70 feet below the sea-level. At Littlebury, in the centre of the village, a boring 218 feet deep has not pierced through the drift, which reaches to 60 feet below the sea-level. As in a well only 60 yards west and slightly higher, the chalk was touched at 6 feet, there must here be a fall of the chalk surface of about 1·2 in 1. Eastward, too, on the other side of the valley, the chalk rises to the surface. The places that have been mentioned range over a distance of 6 miles. How much further the drift-channel may go is not known, neither can we say to what steepness the slope of the underground chalk surface may reach; the slopes given in each case are the lowest possible. The author thinks that the channel has been formed by erosion rather than by disturbance or dissolution of the chalk. After the reading of the paper there was a discussion, in which Dr. Evans, Mr. Clement Reid, Mr. Topley, Mr. J. Allen Brown, Dr. G. J. Hinde, and the author took part.—On the Monian and basal Cambrian rocks of Shropshire, by Prof. J. F. Blake.—On a crocodilian jaw from the Oxford Clay of Peterborough, by R. Lydekker.—On two new species of Labyrinthodonts, by R. Lydekker.

Linnean Society, March 20.—Mr. W. Carruthers, F.R.S., President, in the chair.—After reading the minutes of the last meeting, the following resolution, moved from the chair, was unanimously adopted:—"On the occasion of a gift, from Mr. Crisp, of a handsome oaken table for the meeting-room, the Society desires to record its deep sense of the valuable services rendered by that gentleman, not only as Treasurer, but by numerous acts which are not generally appreciated because they are practically unknown to the Fellows."—Prof. P. Martin Duncan, F.R.S., exhibited several specimens of *Desmophyllum cristagalli* obtained from an electric cable at a depth of 550 fathoms. Though showing great variation in the shape and nature of the wall, the specific characters of the septa were maintained. The core, extending as a thin lamina far beyond the peduncle, had no connection with the septa. A section of *Caryophyllia clavus* showed theca between the septa, and a section of *Lophohelia prolifera* exhibited a true theca extending beyond the septa.—Mr. E. B. Poulton, F.R.S., exhibited some Lepidopterous larvæ showing the variation in colour induced by natural surroundings; and some lizards, in spirit, from the West Indies, showing the pineal eye very distinctly.—In continuation of a former paper on the external morphology of the Lepidopterous pupa, Mr. Poulton gave a detailed and interesting account of the sexual differences observed in the development of the antennæ and wings.—Prof. G. B. Howes read a paper on the intestinal canal of the Ichthyopsida, with especial reference to its arterial supply. He described certain arteries hitherto unrecorded, and some variations he had found in them in the Frog and Salamander. The artery known in the Elasmobranchii as the inferior mesenteric, was shown to belong to

the superior mesenteric series. Discussing the morphology of the intestine and its derivates, the author defined the large intestine of the Pisces more precisely than had hitherto been done, and showed that the appendix digitiformis of the Elasmobranchs must be regarded as homologous with the appendix vermiformis of mammals, and that a short cæcum coli is present at any rate in the Batoidei. The anatomical relationships of the appendix digitiformis were described in certain Elasmobranchs for the first time, and some notes were added upon the cæcum and large intestine among Teleosteans.—An interesting paper was then read by Mr. R. A. Grimshaw, on heredity and sex in the honey-bee.

PARIS.

Academy of Sciences, March 24.—M. Hermite in the chair.—M. Mascart presented a note on a direct-reading transmission dynamometer with a photographic registering arrangement, and also one on the Observatory at Tananarivo, setting forth some of the meteorological work to be undertaken in this new Observatory.—M. Berthelot, in a paper on the condensation of carbonic oxide, and on the penetrability of glass by water, says that he has been unable to obtain evidence of the transmission of water through glass under the influence of the silent discharge, and finds that the carbonic oxide is truly condensed into a body which rapidly takes up moisture from the air.—Under agricultural chemistry, M. Th. Schlœsing makes some remarks relative to the subject of M. Berthelot's observations on the reactions between soils and atmospheric ammonia, and discusses the differences of opinion existing between them.—M. L. Ranvier, in microscopical observations of the contraction of living muscular fibres striated and unstriated, has contrived method by which muscles may be excited whilst being viewed under a microscope, and from comparative observations of muscular elements in repose and contracted, finds that the homogeneous period and the inversion imagined by Merckel does not exist.—On the regulation of the motion of governors by an auxiliary dynamo, by M. A. Ledieu.—On the Cretaceous Echinodermata of Mexico, by M. Cotteau. Descriptions are given of six specimens received from Mexico. The specimens are interesting both from a zoological and geological point of view, since they determine the age of the strata in which they were found.—In studies on the capture theory of periodic comets, M. O. Callandreau extends the elaborate work done by M. Tisserand on the same subject.—On the discovery of a remarkable transcendental function, by M. Fredholm.—On the invariants of a class of equations of the first order, by M. Z. Elliot.—Relation between the volume, the pressure, and the temperature of different vapours, by M. Ch. Antoine.—Comparative study of specific inductive power, and of the conductibility of spaces filled with rarefied air, by M. James Moser. From the study of these properties with spaces containing air in three states of rarefaction—namely, (1) at a pressure of 10 mm. of mercury, (2) at 1 mm. pressure, (3) with an extreme vacuum—the author deduces that while the conductibility varies the specific inductive power remains constant.—Electrolysis of a mixture of two salts in aqueous solution, note by M. L. Boullevigne. Using a mixture of Zn and Cu salts, it is found that the composition of the brass deposited varies rapidly with the intensity of the current employed, contrary to Buff's law. Considering the variation to be due to the chemical action of the sulphate of copper upon the zinc in the alloy deposited, and that the amount of this action is proportional to the time, an expression is found which allows the composition of the alloy obtained with any given intensity to be calculated with a fair degree of accuracy as tested by experimental results. — A new method of preparation of betaïnes, by M. E. Duvillier. The author uses a reaction similar to that by means of which M. Schützenberger obtained the leucines synthetically; an ethereal iodide is caused to act upon the zinc salt of an amide acid in the presence of zinc oxide.—Titration of acetone by the iodoform reaction, by M. G. Arachequesne.—On callose, a new fundamental substance existing in cell membranes, by M. Louis Mangin.—The estimation of fatty matter in milk, by M. Lezé. 100 parts of milk are heated in a flask with a graduated neck till the mixture becomes brown, ammonia is added till the whole becomes clear, the fatty matter rising to the top and its volume being read off on the graduated neck.—On new forms of crystallized silica, note by MM. Michel-Lévy and Munier-Chalmas.—The solubility of some substances in sea-water, by M. J. Thoulet.—On the development of siliceous sponges and the conformation of leaflets among the sponges, by M. Yves Delage.—On the physiological mechanism of hatching, sloughing, and metamorphosis among Orthopterous insects of the Acridean family, by M. J. Kunckel d'Herculais.—On the great sand dunes of the Sahara, note by M. G. Rolland.—On the gypseous formations of the Paris basin, and on the siliceous deposits which have replaced the gypsum, by M. Munier-Chalmas.—On the physiological action of arsenietted hydrogen, by MM. F. Joly and B. de Nabias.—On the diarrhœic action of cholera cultures, by M. N. Gamaleia.—On the vibration of the earth at Chung-Hai and the movements of the compass at Zi-Ka-Wei during this vibration, by M. Chevalier. It is remarked from observations that the vibrations of the earth are unaccompanied by magnetic disturbances.

BERLIN.

Physiological Society, March 14.—Prof. du Bois-Reymond, President, in the chair.—Dr. Heymans spoke on myelin, giving a concise account of the numerous chemical and scanty microscopical investigations of what Virchow had designated as myelin-formations in peripheral nerves. From a chemical point of view the controversy had turned chiefly upon the existence or non-existence of Liebreich's protagon. The speaker had made investigations on frogs' nerves, from which he concluded that both protagon and lecithin are present in them, and that myelin-formations are due to imbibition, with simultaneous production of an external membrane.—Dr. Goldscheider gave an account of his researches on the sensitiveness of the articular surfaces of joints, based upon experiments on the tibial and metatarsal joints in rabbits. It appeared that the sensitiveness was dependent not so much upon the irritability of the surfaces of the joints, as of that of the epiphyses. The greatest effect was produced by direct stimulation of the marrow of the respective bones, while stimulation of the compact bone-substance showed that this was quite insensitive.

NEW LIGHT FROM SOLAR ECLIPSES.

New Light from Solar Eclipses; or Chronology corrected by the Rectification of Errors in the received Astronomical Tables. By William M. Page. With an Introduction by the Rev. J. Brookes, D.D. (St. Louis: Barns Publishing Co., 1890.)

THIS is a book with a considerable portion of which we can have no concern, for it treats largely of theological matters of a disputed kind. It is the production, no doubt, of a devout and pious mind, but of one not scientifically trained. Indeed, we are informed, in an introduction by a St. Louis divine, that it is "written by a brother actively engaged in the ordinary pursuits of life," and an attempt is made to enlist our sympathies with the author on that account. This appeal would have been more effectual if the scientific conclusions at which the author has arrived, and for which he hopes to gain attention, were put forward either with more modesty on his own part, or with greater respect for recognized authorities.

But the contrary is the case. Our prejudices are not respected, and while the crudest statements are made on the smallest possible evidence, the work so bristles with errors that it is difficult to present typical examples. We should have been tempted to leave this volume to the obscurity it merits from a scientific point of view, but for two circumstances. One is, that this book will probably circulate largely among readers not qualified to judge of the rashness of statement and inaccuracy of detail that characterize its astronomical portion, and that consequently a very erroneous and exaggerated opinion may be formed of the character and amount of the errors that still exist in one of the most exact of sciences. The second inducement to look a little closely into its pages is this: that another and more instructed class of readers may imagine that on matters of chronology astronomy speaks with an uncertain sound, and consequently be led to undervalue the very substantial advantages that history has derived from astronomical sources.

The main object of the book is the arrangement of a system that shall bring the narrative contained in the Gospels into the chronological order conceived by the author as correct, and to render consistent, the facts recorded in sacred and secular history, with this system. How far this method and system will satisfy competent theological critics it is, as we have said, not our duty to inquire; we can only hope that the service rendered to religion is greater than that to science, for from the latter point of view we have no hesitation in saying that his theory is erroneous in its conception and unwarranted in its application.

The means employed to produce this chronological harmony is based on the assumption that the places of the sun and moon cannot be correctly computed for distant dates from the existing tables, and that consequently additional terms, empirically determined, must be introduced. This new theory had best be described in the author's own words, for fear we should not do it justice:—

"Our present lunation is too long by a fraction of a second, amounting in the course of a century, to about six minutes of time. In the same length of time, the sun's anomaly is too long by about seven minutes ten seconds of space, the moon's anomaly too long by eight minutes twenty seconds of space, and the sun's mean distance from the node is too short by about eight minutes thirty-five seconds of space."

After an attentive perusal we have not been able to discover any additional explanation or reason for the introduction of these terms. Neither have we discovered to what assumed values of the mean longitude, the mean anomaly, and the argument of latitude these corrections are to be applied. The only references to authorities are apparently those of Baily's "Tables" and Fergusson's "Astronomy," and the author does not appear to have had access or thought it worth while to examine more modern and trustworthy sources. We cannot be quite sure that we have described correctly the elements of the lunar and solar orbits to which these corrections are to be made, but it is asserted that, when introduced into the tables, all the eclipses recorded by the ancients can be represented correctly within a few minutes of time. It is much to be regretted that no rigorous comparison between the observed and computed times of all the ancient eclipses has been attempted, in order that a correct judgment might be formed of the value of this assertion. This was the more necessary as the few cases selected are, we think, very infelicitous, and the incapacity of modern tables to represent these eclipses is unjustifiably, but no doubt unintentionally, exaggerated.

It is curious to notice that the author does not recognize any other criterion of accuracy than the possibility of satisfying these ancient eclipses, the records of which are so imperfect, and the interpretation so doubtful, that they are gradually being discarded in the discussion of the one question for which they at one time seemed peculiarly fitted—namely, the determination of the amount of the secular acceleration of the moon's mean motion. The whole mass of modern observation is ignored. The careful records of eclipses made at Bagdad and Cairo in the ninth and tenth centuries share the same fate. It would seem that any observation made after the first half of the first century does not appear to the author to possess any value.

It will scarcely be believed that this is a correct description of the author's method. No one will imagine that any sane man would attempt to construct a lunar theory from ancient eclipses alone, and expect that the results at which he has arrived will be generally admitted, because, forsooth, he is able to represent a few facts by the introduction of nearly as many variables. It is true that the tables founded on this vicious reasoning do not appear in their integrity, and probably do not exist; but there are given many pages of computation, which are well calculated to mislead the uninstructed, and to give an air of accuracy to the results, to which they are not entitled. We can imagine nothing better adapted to bring astronomy into disrepute with thoughtful, but not mathematically trained minds, than the unwarranted conclusions presented in the slovenly manner in which they appear here.

Some grounds must be given for the severe stricture here passed, and the only difficulty is to select the most fitting examples from so much worthless matter. On p. 18 the author says: "It is considered sufficiently near to the truth, if our calculations came within *a few hours* of the time and near enough to the quantity of the eclipse to identify it as being in all probability the obscuration mentioned by the historian in connection with a certain event." The italics are our own, and the statement to which they call attention is absolutely a misrepresentation. It is scarcely necessary to say in these columns that no astronomer of repute would be satisfied with a discrepancy of anything like this amount between history and computation in any case in which the phenomenon is clearly indicated and accurately described. In the annexed table is given the comparison of the computations of various astronomers of the times of historic eclipses with the recorded times. To keep the table to a moderate length it is confined to those dates between which the examples have been worked out by the writer. In estimating the accuracy of representation, there are two circumstances to be taken into account. One is that an eclipse, being a phenomenon the exact time of whose occurrence could not be accurately predicted by the observer or recorder, must have been in progress some time before detection, or, all observations of the first geometrical contact, the phase computed from the tables, would be observed too late; and though the error from this cause would not be so large in the observation of the end of the total phase, it is probable that this phenomenon would be recorded too soon. The other circumstance is that we cannot regard Ptolemy, from whose work the times here given have been taken, as a totally unprejudiced witness. He was anxious to establish a theory, and it is probable that he selected those instances which most nearly fitted his preconceived system. In other words he may have—what is not unknown in these days —rejected a discordant observation.

Date.	Phase given in "Almagest."	Recorded Greenwich mean time.	Greenwich mean time computed by: Newcomb.	Zech.	Oppolzer.	Ginzel.
		h. m.	h. m.	h. m.	h. m.	h. m.
−490, April 25 ...	Middle	8 27	8 17	7 50	7 53	7 35
−382, Dec. 22 ...	Beginning	15 35	15 52	16 19	16 15	16 7
−381, June 18 ...	Beginning	5 8	4 25	4 54	5 9	4 40
−381, Dec. 12 ...	Beginning	5 56	4 57	6 30	6 18	6 14
−200, Sept. 22	Beginning	3 23	2 57	—	—	—
	End	6 25	5 55	6 29	6 24	6 14
−199, Mar. 19 ...	Beginning	9 29	8 51	9 22	9 20	9 9
−199, Sept. 11 ...	Middle	12 22	12 3	12 34	12 28	12 18
−173, April 30	Beginning	10 48	10 4	10 36	10 16	10 24
	End	13 31	12 45	13 12	13 20	13 3
−140, Jan. 27 ...	Beginning	8 7	6 44	7 8	7 6	7 5
+125, April 5 ...	Middle	6 30	6 36	6 59	6 54	6 51

It is needless to point out there are no discrepancies of a few hours between the tabular and observed facts, and that the grave charge of the lack of accuracy is unsustained. The circumstances of two of these eclipses have been worked out by the author with some pretence of detail, employing his "new and corrected tables." For these two eclipses, − 382, Dec., and − 200, Sept., he gives the London mean times of the true full moon 15h. 56m. and 3h. 16m. respectively. There is no attempt to determine the exact phase observed, and it may be remarked that the longitude given for Babylon is grievously in error. These two eclipses have been selected with the particular purpose of demonstrating that no secular acceleration of the moon's motion exists. This selection, with this view, is unhappy. With regard to the earlier eclipse, it is very doubtful if it was really seen at Babylon. The account given in the "Almagest" ("Halma," p. 275) rather suggests that Athens, or one of the Ionic colonies, was the place of observation, since the description of the date is by means of the Greek calendar; and Hipparchus says that this eclipse with the two immediately following are added to the catalogue of the Babylonian eclipses as though they had been observed in that place (ὡς ἐκεῖ τετηρημένας γεγονέναι). This suggestion that the record of the eclipse was made elsewhere than at Babylon is strengthened by the addition of the note that "the moon set eclipsed." In an eclipse which commenced only half an hour before the setting of the moon, these words would have little meaning, but if the note was added by the observer at Athens, its purpose is intelligible, for the eclipse would be more than half over before the moon touched the horizon. It is very possible, therefore, that some allowance for longitude was made by Hipparchus, but with such a doubt overhanging the recorded time of observation, the selection of this eclipse from the long catalogue collected by Ptolemy gives a very doubtful support to any hypothesis. The second eclipse quoted was doubtless observed at Alexandria, but if Hipparchus is correctly rendered by Ptolemy, he is made to say that the eclipse began half an hour before the moon rose. The record, therefore, refers to a calculated, and not an observed, phenomenon, and on that ground alone should not have been selected.

But it is in solar eclipses, the total phase being confined to a comparatively narrow zone of country, that the feebleness of the author's method is most conspicuously exhibited. The eclipse known as that of Xerxes will serve for an example. To adequately explain the circumstances as recorded by Herodotus and Aristides has exercised the ingenuity, but baffled the efforts, of many experts. It offers no difficulties to Mr. Page, though we cannot think that his rendering will be generally appreciated. Herodotus's description runs, "The army having come out of their winter-quarters in the opening of spring." In the latitude of Sardis the opening of spring could hardly be put as late as April 18, but this is the date selected by Mr. Page, because on that day −480 there was undoubtedly a total eclipse of the sun. The writer does not mention, what is equally the fact, that the shadow of the moon first touched the earth in the Indian Ocean, passed over the Himalayan peninsula, through China, and disappeared in the Pacific. Such a path is totally inadequate to explain the further description of Herodotus, that "night came on instead of day."

A still greater absurdity is introduced when the author wishes to prove that the death of Augustus happened in the year 13, by means of a solar eclipse which is said to have occurred just before the death of that Emperor. He

finds that there was a solar eclipse on 13, April 28, and an attractive woodcut is given showing the track of the shadow passing over Rome. As a matter of fact, this eclipse began in the Pacific, touched the continent of America about Vancouver, and passed over Canada to the Atlantic: the whole of its path is confined to "regions Cæsar never knew." But the list of false deductions is too long and too uninteresting to pursue any further: exact astronomy can lend no support to the chronological system here developed.

WILLIAM E. PLUMMER.

THE EVOLUTION OF SEX.

The Evolution of Sex. By Prof. Patrick Geddes and J. Arthur Thomson. With 104 Illustrations. (London: Walter Scott, 1889.)

THIS book, say the authors in the preface, has "the difficult task of inviting the criticism of the biological student, although primarily addressing itself to the general reader or beginner." In attempting to meet these two interests the authors have aimed high: they have aimed at producing a classic. They have brought to the task—as indeed their names guarantee—a wealth of knowledge, a lucid and attractive method of treatment, and a rich vein of picturesque language. The illustrations are pertinent, and sometimes very good. The index and table of contents are copious, and the summaries and references to literature at the end of each chapter are most useful. In matters of history they are especially good, and advanced biological students will find the abstracts of the views of Eimer, Weismann, Brooks, Hertwig, Haeckel, Wallace, Spencer, Geddes, and many others exceedingly useful. But as writers for the general public the authors have serious if not prohibitive disadvantages.

General readers demand, with right, that those who speak to them with the voice of authority shall give them the authoritative views. Controversial matter they are only remotely interested in, and when it cannot be avoided they must have it carefully distinguished from matter beyond controversy. These authors are controversialists from the first page of their book to the last: they are partisan controversialists offering their wares and their wisdom as accredited doctrine and determined result. This is no quarrel with the views of the authors. Prof. Geddes and Mr. Thomson are workers well able to command the attention of biologists for their contributions to any controversy. It is a quarrel with the offering of personal views, generalizations, and theories as final, in a series "designed to bring within the reach of the English-speaking public the best that is known and thought in all departments of modern scientific research."

As is the fashion with neo-Lamarckians, the authors delight in obtruding their misconceptions of Darwin. Take, for instance, the following statements:—

"Arguing from the bad effects of close-breeding among higher animals, Darwin and others have called attention to the numerous contrivances among plants which are said to render self-fertilization impossible. It must again be said that this survival of a very old way of explaining facts—in terms of their final advantage—is not really a causal explanation at all" (p. 74).

Or, again, on p. 27:—

"As a special case of natural selection Darwin's minor theory (*i.e.* sexual selection) is open to the objection of being teleological, *i.e.* of accounting for structures in terms of a final advantage. It is quite open to the logical critic to urge, as a few have done, that the structures to be explained have to be accounted for before, as well as after, the stage when they were developed enough to be useful. The origin, or in other words, the fundamental physiological import, of the structures, must be explained before we have a complete or adequate theory of organic evolution."

Now there can be no doubt of the question here at issue. Readers of NATURE may remember that some time ago (NATURE, December 12, 1889, p. 129) Prof. Ray Lankester *à propos* of Cope's supposed contribution to the theory of natural selection,[1] asked: "How can Mr. Cope presume to tell us this? Who has ignored it? When? and where?" It is clear that Prof. Geddes and Mr. Thomson imagine that Darwin has ignored this, and that he has done so in his theory of sexual selection, and in his accounts of contrivances in plants to prevent self-fertilization. In a set of works the definite and reiterated purpose of which is to show (1) that variations do occur, (2) that from these, by selection, varieties, species, organs are elaborated and adapted, it is fortunately easy to find chapter and verse conclusive against the view that Darwin could have imagined that selection teleologically causes the variations that give it scope. Will Prof. Geddes and Mr. Thomson refer to the "Descent of Man" (the writer has the second edition before him)? On p. 240 it is written:—

"Not only are the laws of inheritance extremely complex, but so are the causes which induce and govern variability. The variations thus induced are preserved and accumulated by sexual selection."

Will Prof. Geddes and Mr. Thomson refer to the "Fertilization of Orchids" (also second edition)? On p. 284 it is written:—

"Thus throughout nature almost every part of each living being has probably served in a slightly modified condition for diverse purposes, and has acted in the living machinery of many ancient and distinct specific forms."

Or, again, on the same page:—

"This change" (labellum assuming its normal position) "it is obvious might be simply effected by the continual selection of varieties which had their ovaries less and less twisted; but if the plant only afforded varieties with the ovarium more twisted, the same end could be attained by the selection of such variations until the flower was turned completely round on its axis."

Can there be the faintest suspicion that the man who wrote these sentences did not distinguish between the material for selection and the causes producing that material? One more quotation from the authors to show how they misunderstand Darwin's spirit and writings:—

"The first of these is the still curiously prevalent opinion that, when you have explained the utility or the advantage of a fact, you have accounted for the fact, *an opinion which the theory of natural selection has done more to foster than to rebuff. Darwin was indeed himself characteristically silent* in regard to the origin of sex as well as of many other 'big lifts' in the organic series" (p. 126).

[1] The key-note of Cope's imagined contribution was, "Selection cannot explain the origin of anything."

What do the authors mean? Their erudite and careful statements of the position of many foreign writers emphasize their failure to represent the position of the author of the "Origin of Species."

The authors think that the problems and questions relating to sex, problems and questions carefully and ingeniously analyzed by them, "are in final synthesis all answerable in a sentence." Morphological questions are at base, they say, physiological; and physiological questions are ultimately referable to the metabolism of protoplasm, as Prof. Burdon-Sanderson pointed out last autumn. This metabolism is double: it consists on the one hand of anabolic, constructive, elaborative processes—processes attended with the storage of energy; and on the other hand of katabolic, destructive, disintegrating processes—processes attended with the liberation of energy. These processes are complementary; in living protoplasm they seem for the most part coincident. Losing sight of the coincidence the authors have seized on the antithesis; the idea has grown upon them till they see a rhythm of anabolism and katabolism swinging through organic nature and producing—well, producing nearly everything.

Take, for instance, secondary sexual characters. Males are frequently lithe, active, aggressive, gorgeously coloured and decorated. Females are often sluggish, vegetative, passive, and soberly coloured. These characters, according to Geddes and Thomson, occur because males have a male or katabolic diathesis, because females have a female or anabolic diathesis.

"Brilliancy of colour, exuberance of hair and feathers, activity of scent glands, and even the development of weapons, are not and cannot be (except teleologically) explained by sexual selection, but in origin and continued development are outcrops of a male as opposed to a female constitution" (p. 22).

It is impossible to follow in detail and state the innumerable objections to this explanation. Do the authors suppose a male diathesis explains the ascending series of horn and antler development? Can it in any way account for "interference" colours, which play so large a part in the adorning of males? Are women less female when they have radiant complexions and abundant tresses? What physiological reason is there for believing that skeletal weapons and scent glands, or the crystals in anthers, are due to the katabolism of "exuberant maleness," while menstruation and lactation are means of getting rid of "anabolic surplus?"

Parthenogenesis occurs in groups of animals where the anabolic rhythm is dominant. Sex itself appears when katabolic conditions preponderate. And this is why flowers so often are situated at the end of the vegetative axis; this is furthest from the source of nutrition; the flower occupies a katabolic position, and is often the plant's dying effort (p. 226). Alternation of generations is a special example of the rhythm. Thus, but the authors do not cite this example in this connection, the tiny sexless and spore-bearing stalk parasitic on the moss-plant is the anabolic vegetative generation, while the conspicuous moss-plant is the sexual or katabolic generation—the generation peculiarly connected with starvation! It is obvious that the authors are nothing if not original. But the real value of the book must not be lost sight of in quotations from it. The chapters on the "Determination of Sex," on "Sex Elements," and on "Growth and Reproduction," are very suggestive. But indeed, to biologists the greater part of the book and its theories must be useful and suggestive. It is only the general public that must be warned off.

It is very much to be regretted that the authors have included a discussion of certain social and ethical problems absolutely unconnected with the title of their book. If such matters are to be discussed *coram populo*, it is only fair that explicit information should appear on the title-page.

P. C. M.

THE QUICKSILVER DEPOSITS OF THE PACIFIC SLOPE.

Geology of the Quicksilver Deposits of the Pacific Slope. By G. F. Becker. Pp. 486, and Atlas of xiv. folio Plates. (Washington: Government Printing Office, 1888.)

AMONG the numerous mineral treasures of California none are of more interest than the deposits of mercury ore which occur at intervals along the greater part of the Coast Range from the Mexican boundary to Clear Lake, in lat. 39° N., a distance of more than 200 miles. This region, together with the district of Steamboat Springs in Nevada, has been carefully examined by the division of the United States Geological Survey under the charge of Mr. G. F. Becker, and the results are now presented in another of the handsome quarto series of monographs published by Major Powell, the head of the Survey.

The discovery of mercury in California preceded that of gold; the most productive locality, New Almaden, near San José, at the south end of the Bay of San Francisco, having been known for about 65 years, while the actual mining was commenced under a grant from the Mexican Government shortly before the cession of the country to the United States. In its earlier years the mine was extremely profitable, and the long judicial controversy that ensued before the title was satisfactorily established occupies a prominent place among the records of American mining litigation. The maximum production of 47,194 flasks of 76½ pounds each was realized in 1865, but in 1886 it was reduced to 18,000 flasks, the total for the period 1850–86 being 853,259 flasks, or about two-thirds of the produce of the Spanish Almaden. The total produce of the Californian mines, which was about 80,000 flasks in 1877, declined to 30,000 in 1886.

The second mine in point of importance, known as New Idria, is about 70 miles in a south-easterly direction from New Almaden, the ore, cinnabar, occurring under conditions similar to those in the latter mine—namely, in very irregular groups of fissures in metamorphic strata, which pass into others containing Neocomian fossils of the genus *Aucella*. These were succeeded by other Cretaceous and Tertiary formations up to the Miocene, the close of the latter period being marked by an upheaval and the commencement of volcanic activity. The ore deposits are closely related to the latter, and are probably nearly all, if not entirely, of post-Pliocene origin.

In the Clear Lake region, in lat. 39° N., which adjoins the group of volcanic cones known as Mount

Konocte (or Uncle Sam) hot springs and solfataras are abundant in a small area of basalt of comparatively recent origin. The most important of these, known as the Sulphur Bank, was at first worked for sulphur, but, on getting below the surface, cinnabar was found in the decomposed basalt, and for some years it produced large quantities of mercury, up to 11,152 flasks in 1881; but latterly the yield has fallen off, being only 1449 flasks in 1886.

The Redington Mine, adjoining Knoxville, about 25 miles south-east of Clear Lake, was discovered in making a cutting for a road, and has been worked since 1862, and has produced nearly 100,000 flasks of mercury, a quantity which has only been exceeded by the mines of New Almaden and New Idria. In 1886 the yield had fallen to 409 flasks, the immense irregular body of ore at the surface having changed in depth to some narrow veins following fissures in the metamorphic Neocomian strata. These are to a large extent converted into serpentine; and a black opal, known as quicksilver rock, accompanied the ore, which was remarkable as consisting largely, in the upper workings at least, of amorphous black sulphide of mercury, or meta-cinnabar, a mineral that was there recognized in quantity for the first time. This deposit is considered to be the result of the action of hot springs in connection with an adjacent mass of basalt—springs which are now dormant except in so far that sulphur gases are given off and sulphur crystals are deposited in the old workings, where a comparatively high temperature, exceeding 100° F., prevails.

The Steamboat Springs in Nevada, near the Comstock lode, have been also studied by the author. These, although presenting no deposits of commercial value, are interesting from the light they cast upon the phenomena of the formation of mineral veins, and have therefore been carefully investigated by several observers, including the late Mr. J. A. Phillips, F.R.S., and M. Laur, of the École des Mines. The author considers that the main source of the ore in the Comstock lode is the diabase forming the hanging wall, and that the mineral contents were extracted from this pre-Tertiary eruptive mass by intensely heated waters charged with alkaline carbonates and sulphides rising from great depths, and that a similar origin may properly be attributed to all the cinnabar, pyrites, and gold found in the mercury-mines of the Pacific slope, having been brought in as solutions as double sulphides of metal and alkalies. The original source must have been either the fundamental granite of the country, or some *infra*-granitic mass, it being extremely improbable that they were extracted from any volcanic rock at or near the surface. In connection with this subject, the author has made a series of interesting experiments on the relations of the sulphide of mercury to that of sodium, which show that mercuric sulphide is freely soluble in aqueous solutions of sodium sulphide, although the contrary has repeatedly been asserted. Mercuric sulphide may be precipitated from sulpho-salt solutions in many ways, particularly by excess of sulphuretted hydrogen, by borax and other mineral salts; by cooling, especially in the presence of ammonia, and by dilution. In the latter case, a certain quantity of metallic mercury separates as well as the sulphide, indicating one of the methods by which the native metal has been produced in Nature.

In addition to the mines specially described, the author has extended his study of the subject to a consideration of the principal mercury-mines other than those of America, partly from personal investigation in Spain and Italy, and partly with the help of other observers and published accounts. He expresses a very decided opinion against the supposed substitution origin of the Almaden deposits, considering them to be essentially of a vein-like character, the cinnabar being deposited in fissures or interstitial cavities in sandstone previously existing. This latter conclusion is substantially similar to that arrived at by the late Mr. J. A. Phillips and the present writer, in a microscopic study of the Almaden ores made some years since. The details of the foreign deposits have been very carefully collected, the comparatively new discoveries of Avala in Servia, and Bakmuth in Southern European Russia, being included. The latter mine, which, at the time the book was completed, was not at work, has since become of considerable importance. The ore, cinnabar, occurs as an impregnation of a bed of carboniferous sandstone from 14 to 17 feet thick, with an average yield of 154 pounds per ton—about 7 per cent.—and the reduction works have a productive capacity of about 10,000 flasks annually.

In conclusion, it is scarcely necessary to state that the whole of the details illustrating the subject have been worked out with the care and fulness which have characterized the author's former monograph on the Comstock lode. Whether mercury-mining in California may be in a declining state, or destined to a revival of its former prosperity at a future time, there can be no question of the high value of the record of the results hitherto obtained, which is contained in the volume it has been our pleasant task to notice. H. B.

OUR BOOK SHELF.

Illustrations of some of the Grasses of the Southern Punjab, being Photo-lithographs of some of the Principal Grasses found at Hissar. By William Coldstream, B.A., Bengal Civil Service. With 38 Plates and 8 pages of Introduction. (London: Thacker and Co. Calcutta: Thacker and Spink. 1889.)

THIS work contains a series of thirty-eight photo-lithographs of the grasses used for agricultural purposes in the southern portion of the Punjab. The tract of country to which it relates lies to the west of Delhi, between the Jumna on the east and the Sutlej on the west. It constituted till recently the civil district of Hissar, which has now been broken up. It has an area of 8500 square miles, and a population of a million and a half. Except along the streams and canals the soil is sterile and sandy, and the crops depend upon the periodical rains. The staple cereals are *Sorghum vulgare* and *Penicillaria spicata*. In its centre is situated the great Government cattle-farm of Hissar, where for many years cattle of the finest Indian breeds have been reared by Government, principally for the supply of the ordnance and transport departments, but also to some extent for distribution through the country, with the aim of improving the commoner indigenous kinds. The *Bir*, or grass-lands, of this great farm are of very wide extent, and in the rainy season a large number of grasses, of more or less value as fodder, grow luxuriantly over its vast parks. The farm has altogether an area of above sixty square miles, and it is mainly from this that the species figured by Mr. Coldstream are taken.

The book is modelled upon the "Fodder-grasses of India," published not long ago, in two volumes, by Mr. Duthie, the director of the botanical department of Northern India, and to Mr. Duthie the author is indebted for the botanical determination of the species. He gives the native name of each plant, and a short account of the extent and manner in which it is used, and as most of them have a wide dispersion, this will be found useful in other dry sub-tropical regions. Out of thirty-seven species, the two great tropical tribes are represented, *Paniceæ* by twelve species, and *Andropogoneæ* by ten, and only three species fall under *Festuceæ*, the tribe to which most of our North European pasture grasses belong. The plates are lithographed from photographs, and do not contain any dissections. Plate III., called *Panicum Crusgalli*, is clearly not that species, but a form of *P. colonum*, another variety of which is figured on Plate II. Mr. Coldstream also has got entirely wrong with his two species of *Cyperus*, figured on p. 38. The left-hand figure, called *Cyperus species*, is evidently *Cyperus Iria*, Linn., a common weed throughout India in rice-fields. The left-hand figure, labelled *Cyperus Tria*, is not in flower. There is no such plant known to botany; *Tria* is doubtless a mistake for *Iria*. The figure is quite unrecognizable, but from the native name appended, "Motha," it is most likely *Cyperus rotundus*.

J. G. B.

Elementary Dynamics of Particles and Solids. By W. M. Hicks, M.A., F.R.S. (London: Macmillan and Co., 1890.)

IN this excellent treatise, extending over nearly 400 pages, the author introduces to the student the principles of dynamics. Although the book is issued under the latter title, it will be found to differ considerably in its treatment from the majority of text-books on the same subject. For instance, the two subjects of statics and kinetics have been considered together, the former being regarded as a special case of the latter. Again, the discussion of force is reserved until an attempt has been made to give an idea of mass and its measurement; thus a preliminary study of momentum finds an early place.

Although the mathematical acquirements of the student of these pages may be limited to a knowledge of the elements of algebra and geometry, he will be able to readily follow the methods adopted in establishing the various results. This the author has kept in view throughout his work, except in a few cases where, in the hope of rendering it useful to a larger circle of readers, he has had recourse to the trigonometrical ratios for examples which he has worked out.

The volume is divided into three portions (1) rectilinear motion of a particle; (2) forces in one plane; (3) plane motion of a rigid body.

One cannot read the first few chapters without observing the care taken by the writer in trying to impart to the student a correct and precise idea of the fundamental units. That this is a very important matter all will agree who have had any experience in teaching or testing students. The most deplorable state of ignorance sometimes exhibited by them, in giving their results in all manner of absurd units, should encourage both teacher and author to make a special effort when dealing with the question of units, fundamental or otherwise.

As the subject of statics is included, an opportunity has been taken of introducing the method of drawing stress diagrams for loaded framework; this will be valuable to engineering students.

Notwithstanding that the writer has forbidden himself the use of the integral calculus, he has been able to establish (in some cases very neatly) many useful results in the two chapters on centre of gravity and moment of inertia, which should be read with care.

Neatness in method characterizes the book throughout and an unusually large number of examples will be found at the end of each chapter.

The work is based on a series of lectures delivered by the author at the Firth College, Sheffield, and many details for which time can generally be found at the lecture table have in this case found their way into the book.

These will help to lessen the individual difficulties of students, and their views of the subject will be enlarged thereby. There can be little doubt that the text-book will have a deservedly favourable reception.

Catalogue of the Fossil Reptilia and Amphibia in the British Museum (Natural History). Part III., containing the Order *Chelonia*. By Richard Lydekker, B.A., F.G.S., &c. (London: Printed by Order of the Trustees, 1889.)

MR. LYDEKKER is to be congratulated on having added one more to the valuable series of catalogues of the palæontological collections in the British Museum which he has compiled during the last few years. Like his previous catalogues, the present work indicates an enormous amount of careful and accurate work, which, however, is of such a special kind that it cannot easily be summarized in a short review.

The extreme difficulty of correlating the fossil forms of Chelonia with the recent, on account of the fragmentary character of many of the remains, is indicated by the fact that, out of the 52 genera and 131 species or varieties described, the author has only been able to place with certainty 18 genera and 10 species amongst existing forms. The classification adopted is to a great extent that followed by Mr. Boulenger in his catalogue of recent Chelonians. The work is illustrated by 53 woodcuts, and abundant references to the bibliography of the group are given. It must be added, as stated in the preface, that "the collection which forms the subject of this Catalogue is particularly rich in Chelonians from the Purbeck Beds of Swanage, the Cretaceous of England and Holland, the Eocene Tertiaries of Warwick, Sheppey, Hampshire, the Isle of Wight, and the older Pliocene of the Siwaliks of India." The last-named beds have yielded the largest tortoise known (*Testudo* [*Colossochelys*] *atlas* of Falconer), the carapace of which measures about six feet in length.

LETTERS TO THE EDITOR.

Systems of "Russian Transliteration."

As one who takes an interest in the Russian tongue, quite apart from the value of the scientific papers published in that language, I may perhaps be allowed to express my regret that the author of "A Uniform System of Russian Transliteration," published in your issue of February 27 (p. 397), has departed in almost every point where it is possible to do so from the system of transliteration which has been in use in England for about a century, and which has, moreover, the advantage of being almost identical with that current in France.

A system of transliteration may be founded on one of two bases—namely, the *empirical*, in which little or no account is taken of the sound of the letters in the foreign language, and the *rational*; in the latter the letters of the foreign language are, where possible, represented by letters or groups of letters which have as nearly as may be the same sound as the original. For instance, Б in Russian would be represented by *B* in English, these two having the same sound. It seems to me that the latter is the most convenient system, and the one which ought to be

generally adopted; the author of this new "uniform system," however, has chosen the other course.

If the author of the "uniform system" had been contented with tabulating the system of transliteration which has been so long in use, he would have earned the gratitude of those devoted to literature, as well as of those who cultivate science. As it is, I am afraid he has merely given the world of art and letters an opportunity for gibes at what they are sometimes pleased to call the narrowmindedness and pedantry of scientific men.

I may, perhaps, be permitted to give a few examples of the defects of the new system; Г in Russian has three sounds, one nearly resembling the English *g*, another very like *h*, and a third guttural sound, to which there is nothing analogous in our tongue. The author proposes to get over this by transliterating Г by *gh*!! The eminent chemist Hemilian thus becomes masked as Ghemilian, whilst Gustavson appears as Ghustavson, and a well-known political character, Gortchakoff, is altered to Ghorchakov'. For comparison, I give these names, and a few others, as transliterated in accordance with the two systems:—

Present system,	New system.
Hemilian	Ghemilian.
Gustavson	Ghustavson'.
Gortchakoff	Ghorchakov'.
Alexéeff	Aleksyeev'.
Gregoreff	Ghrighor'ev'.
Ogloblin	Oghloblin.
Mendeléeff	Mendelyeev'.
Chroushtchoff	Khrushchov'.
Michael	Mikhail.
Joukovsky	Zhukovskič.

Geographical names are even more weird; for example, it becomes somewhat difficult to recognize under the disguise of Nizhniĭ Novghorod and Volgha, the town of Nijni Novgorod and the River Volga. Such words as "Journal" and "Chemie," when occurring in titles, can be at once recognized; this can scarcely be said of them if the new system of transliteration is used, as they become "zhurnal" and "Khimiĭ" respectively.

It is much to be regretted that the Royal Society, the Linnean Society, and the Geological Society should have pledged themselves to adopt this novel "system of transliteration," instead of adhering to the one which has been so long in use. As a Fellow of the Royal Society, I feel very great regret that the Council are going to adopt this system in their publications, as it will seriously detract from the value of their supplementary "Catalogue of Scientific Papers" now in the press, at all events as far as Russian literature is concerned.

No protest of mine, however, can be half so forcible as the unconscious sarcasm of the author himself, in his paper, where he says that "an expression of grateful thanks is due" to two Russians "who have assisted in the arrangement of the system." The names of the Russians are then given, and if my readers will take the trouble to study them by the light of the table for transliteration by the new system, he will see how they express their appreciation of the author's labours by *carefully avoiding* every one of the novelties he has introduced.

CHARLES E. GROVES,
Editor of the *Journal of the Chemical Society*.
Burlington House, March 17.

HAVING in view the increasing importance of Russian to literary and scientific men, it becomes very desirable to have a uniform system of transliteration, such as that recently proposed in your columns.

But, in order to be useful, everyone must agree to conform to it, nor should any such system be adopted off-hand without full discussion of any points which may seem susceptible of improvement.

It seems to me objectionable to indicate the semi-vowels (ъ and ь) by a simple ', and to omit them altogether at the end of a word. They really correspond, to a certain extent, to our *e* (mute); and I would suggest that it would be better to indicate them by a full letter—perhaps *ĕ* for one and *ê* for the other.

March 11. W. F. KIRBY.

ONE or two points in the criticisms on this subject call for some notice before the publication of a more detailed account of the system.

As regards Mr. Kirby's suggestion, the transliteration of the semi-vowels was discussed, but it was not thought advisable to exaggerate their importance by using two letters for them, especially as their use is becoming discontinued in Russia.

When recommending a uniform system, we did not imagine that Mr. Groves or anyone else would infer that this was intended to limit the right of Russians who dwell in England or who write in English to spell their names as they please; we have not asked Messrs. Kelly to apply it to all Russian names in the Post Office Directory or the Court Guide; we should never think of altering such names in ordinary correspondence. Even in catalogues and records, for which this system is intended, the familiar form should of course be quoted with a cross reference, as recommended by us in the clause dealing with proper names.

Mr. Groves asks why we have not tabulated "the system which has been in use in England for about a century." Our efforts began with an attempt to discover such a system, and resulted in the tabulation of a large number of systems, including that employed by Mr. Groves in the *Journal of the Chemical Society*; since, however, no two authors agree in the English symbols intended to represent either the sounds or letters of Russian words, we endeavoured to frame a system combining as far as possible the features of those already in use in England and America.

We are much obliged to Mr. Groves for supplying further illustrations of the desirability of using *gh* for Г; the letter has, of course, more than the three sounds to which he limits it.

The uniformity of "the system which has been so long in use" may be illustrated by the following examples, in which we confine ourselves to the names of chemists, and to the words quoted by Mr. Groves:—

Consulting the "Imperial Gazetteer," Lippincott's "Gazetteer," and Keith Johnston's "Atlas" alone, we find Nijni, Nijnei, Nishnii, Nizhnee, Nijnii, and Nischnii-Novgorod.

One journal is given in Bolton's "Catalogue of Chemical Journals" as

Zhurnal russkova khimicheskova i fizicheskova;

in the *Geological Record* as

Jurnal rosskoi chimitcheskago i phizitcheskago;

and in Scudder's "Catalogue of Serials" as

Zhurnal; russkoye khimitcheskoye i fizitcheskoye.

Hence it is difficult to see why Nizhniĭ and Zhurnal should be unintelligible.

In the Royal Society Catalogue, the *Geological Record*, and Chemical Society's Journal, the same name is spelt Jeremejew, Jeremejeff, Jereméeff. Which of these words represents the pronunciation?

In the Chemical Society's Journal, Wroblewski and Flawitzky correspond to the Wroblevsky and Flavitzsky of Armstrong and Groves' "Organic Chemistry."

The same journal frequently quotes the name Markownikoff where the same Russian letter (and sound) is denoted both by *w* and *ff*, while in the examples of Mr. Groves it is also represented by *v*; here, of course, and in similar cases, the name comes through a German channel.

Mr. Groves transliterates a few names; since, however, in his "rational" system one Russian letter has more than one English equivalent (*v*, *ff*), and one English letter (*e*) has more than one Russian equivalent, while the sound is not correctly represented (*o*, *é*), it is obvious that this is neither "rational" nor a system (it does not profess to be "empirical"; perhaps Mr. Groves will now call it the "graphic method").

Since, moreover, the system recommended by Mr. Groves is not used by him in the Chemical Society's Journal, we hope that he may yet see his way to adopting the one which has now been accepted by so many of the leading English Societies.

"Like to Like"—a Fundamental Principle in Bionomics.

THE following letter has been intrusted to me for seeing through the press, and therefore I deem it desirable to state that it does not constitute the writer's reply to Mr. Wallace's criticism of his paper on "Divergent Evolution." This reply, as previously stated (NATURE, vol. xl. p. 645), will be published by him on some future occasion.

I cannot allow the present communication to appear in these columns without again recording my conviction that the writer is the most profound of living thinkers upon Darwinian topics, and that the generalizations which have been reached by his twenty years of thought are of more importance to the theory of evolution than any that have been published during the post-Darwinian period. GEORGE J. ROMANES.

London, March 10.

I FOLLOW Prof. Lankester in the use of bionomics to designate the science treating of the relations of species to species. If the theory of evolution is true, bionomics should treat of the origin, not only of species, but of genera, and the higher groups in which the organic world now exists.

In his very suggestive review of "Darwinism," by Mr. A. R. Wallace, in NATURE of October 10, 1889 (p. 566), Prof. Lankester refers to "his (Mr. Wallace's) theory of the importance of the principle of 'like to like' in the segregation of varieties, and the consequent development of new species." Prof. Lankester has here alluded to a principle which I consider more fundamental than natural selection, in that it not only explains whatever influence natural selection has in the formation of new species, but also indicates combinations of causes that may produce new species without the aid of diversity of natural selection. The form of like to like which Mr. Wallace discusses is "the constant preference of animals for their like, even in the case of slightly different varieties of the same species," which is considered not as an independent cause of divergence, but as producing isolation which facilitates the action of natural selection. If he had recognized this principle, which he calls selective association, as capable of producing in one phase of its action sexual and social segregation, and in another phase sexual and social selection, he would perhaps have seen that its power to produce divergence does not depend on its being aided by natural selection.

Mr. Wallace's view is very clearly expressed in the following passages, though I find other passages which lead me to think that the chief reason he does not recognize segregation as the fundamental principle in divergence is that he has not observed its relations to the principle of like to like. He says:—"A great body of facts on the one hand, and some weighty arguments on the other, alike prove that specific characters have been, and could only have been, developed and fixed by natural selection because of their utility" ("Darwinism," p. 142). "Most writers on the subject consider the isolation of a portion of a species a very important factor in the formation of new species, while others maintain it to be absolutely essential. This latter view has arisen from an exaggerated opinion as to the power of intercrossing to keep down any variety or incipient species, and merge it in the parent stock" ("Darwinism," p. 144).

I think we shall reach a more consistent and complete apprehension of the subject by starting with the fundamental laws of heredity, and refusing to admit any assumption that is opposed to these principles, till sufficient reasons have been given. Laws which have been established by thousands of years of experiment in domesticating plants and animals, should be, it seems to me, consistently applied to the general theory of evolution. For example, if in the case of domesticated animals, "it is only by isolation and pure breeding that any specially desired qualities can be increased by selection" (see "Darwinism," p. 99), why is not the same condition equally essential in the formation of natural varieties and species? If in our experiments we find that careful *selection* of divergent variations of one stock does not result in increasingly divergent varieties *unless free crossing between the varieties is prevented*, why should it be considered an exaggeration to hold that in wild species "the power of intercrossing to keep down any variety or incipient species, and merge it in the parent stock," is the same. Experience shows that *segregation, which is the bringing of like to like in groups that are prevented from crossing*, is the fundamental principle in the divergence of the various forms of a given stock, rather than *selection, which is like to like through the prevention of certain forms from propagating*; and I think we introduce confusion, perplexity, and a network of inconsistencies into our exposition of the subject, whenever we assume that the latter is the fundamental factor, and especially when we assume that it can produce divergence without the co-operation of any cause of *segregation* dividing the forms that propagate into two or more groups of similars, or when we assume that segregation and divergence cannot be produced without the aid of diverse forms of selection in the different groups. The theory of divergence through segregation states the principle through which natural selection becomes a factor promoting sometimes the stability and sometimes the transformation of types, but never producing *divergent* transformation except as it co-operates with some form of isolation in producing segregation; and it maintains that, whenever variations whose ancestors have freely intergenerated are from any combination of causes subjected to persistent and cumulative forms of segregation, divergence more or less pronounced must be the result. The laws of heredity on which this principle rests may be given in the three following statements:—

(1) Unlike to unlike, or the removal of segregating influences, is a principle that results either in extinction through failure to propagate, or in the breaking down of divergences through free crossing.

(2) Like to like, when the individuals of each intergenerating group represent the average character of the group, is a principle through which the stability of existing types is promoted.

(3) Like to like, when the individuals of each group represent other than the average character of the group, is a principle through which the transformation of types is effected.

In my paper on "Divergent Evolution" (Linn. Soc. Journ., Zoology, vol. xx. pp. 189-274), I pointed out that sexual and social instincts often conspire together to bring like to like in groups that do not cross, and that in such cases there will be divergence even when there is no diversity of natural selection in the different groups, as, for example, when the different groups occupy the same area, and are guided by the same habits in their use of the environment. There is reason to believe that under such circumstances divergence often arises somewhat in the following way. Local segregation of a partial nature results in some diversity of colour or in some peculiar development of accessory plumes, and through the principle of social segregation, which leads animals to prefer to associate with those whose appearance has become familiar to them, the variation is prevented from being submerged by intercrossing. There next arises a double process of sexual and social selection, whereby both the peculiar external character and the internal instinct that leads those thus characterized to associate together are intensified. The instinct is intensified, because any member of the community that is deficient in the desire to keep with companions of that kind will stray away and fail of breeding with the rest. This process I call social selection. The peculiarity of colour or plumage is preserved and accumulated, because any individual deficient in the characteristic is less likely to succeed in pairing and leaving progeny. This latter process is sexual selection. It can hardly be questioned that both these principles are operative in producing permanent varieties and initial species; and in the circumstances I have supposed, I do not see how the process can be attributed to natural selection. Varieties thus segregated may often develop divergent habits in their use of the environment, resulting in divergent forms of natural selection, and producing additional changes; but so long as their habits of using the environment remain unchanged, their divergencies cannot be due to natural selection.

Mr. Wallace's very interesting section on "Colour as a Means of Recognition," taken in connection with the section on "Selective Association," already referred to, and another on "Sexual Characters due to Natural Selection," offers an explanation of "the curious fact that prominent differences of colour often distinguish species otherwise very closely allied to each other" (p. 226). His exposition differs from mine in that he denies the influence of sexual selection, and attributes the whole process to natural selection, on the ground that "means of easy recognition must be of vital importance" (p. 217). The reasoning, however, seems to me to be defective, because the general necessity for means of easy recognition is taken as equivalent to the necessity for a specialization of recognition marks that shall enable the different varieties to avoid crossing. In the cases I am considering, there is, however, no advantage in the separate breeding of the different varieties, and even in cases where there is such an advantage (as there would be if the variety had habits enabling it to escape from competition with the parent stock, but only partially preventing it from crossing with the same), it does not appear how this advantage can prevent the individual that is defective in the special colouring from following and associating with those that are more clearly marked. The significant part of the process in the development of recognition marks must be in the failure of such individuals to secure mates, which is sexual selection; or in the unwillingness of the

community to tolerate the company of such, which might be called social selection.

It is often assumed by writers on evolution that permanent differences in the methods in which a life-preserving function is performed are necessarily useful differences. That this is not so may be shown by an illustration drawn from the methods of language. The general usefulness of language is most apparent, and it is certain that some of the laws of linguistic development are determined by a principle which may be called "the survival of the fittest;" but it is equally certain that all the divergences which separate languages are not useful divergences. That one race of men should count by tens and another by twenties is not determined by differences in the environments of the races, or by any advantage derived from the difference in the methods. So easy recognition of other members of the species is of the highest importance for every species; but difference in "recognition marks" in portions of a species separated in different districts of the same environment is no advantage. Under the same conditions, habits of feeding may become divergent; but, since any new habit that may be found advantageous in one district would be of equal advantage in the other district, the divergence must be attributed to some initial difference in the two portions of the species.

I have recently observed that, of two closely allied species of flat-fish found on the coasts of Japan, one always has its eyes on the right side, and the other always on the left. As either arrangement would be equally useful in the environment of either species, the divergence cannot be considered advantageous.

Osaka, Japan. JOHN T. GULICK.

Self-Colonization of the Coco-nut Palm.

THE question whether the coco-nut palm is capable of establishing itself on oceanic islands, or other shores for the matter of that, from seed cast ashore, was long doubted; and if the recent evidence collected by Prof. Moseley, Mr. H. O. Forbes, and Dr. Guppy, together with the general distribution of the palm, be not sufficient to convince the most sceptical person on this point, there is now absolutely incontrovertible evidence that it is capable of doing so, even under apparently very unfavourable conditions.

In the current volume of NATURE (p. 276) Captain Wharton describes the newly-raised Falcon Island in the Pacific; and in the last part of the Proceedings of the Royal Geographical Society, Mr. J. J. Lister gives an account of the natural history of the island. From this interesting contribution to the sources of insular floras we learn that he found two young coco-nut palms, not in a very flourishing condition, it is true; but they were there, and had evidently obtained a footing unaided by man. There were also a grass, a leguminous plant, and a young candle-nut (Aleurites), on this new volcanic island—a very good start under the circumstances, and suggestive of what might happen in the course of centuries.

W. BOTTING HEMSLEY.

On Certain Devonian Plants from Scotland.

I AM indebted to Mr. James Reid, of Allan House, Blairgowrie, Scotland, for the opportunity to examine a collection of fossil plants obtained by him from the Old Red Sandstone of Murthly and Blairgowrie in Perthshire, some of which have been noticed by Dr. Geikie in his "Text-book of Geology."

The collection is remarkable for the striking resemblance of the matrix and the contained vegetable debris to those of the lower part of the Gaspé sandstones of Logan, and the species of plants are, so far as can be determined, the same.[1]

Psilophyton princeps largely predominates, as in Gaspé, and is represented by a profusion of fragments of stems and branches, and more rarely by specimens of the rhizoma and of the sporocarps. *P. robustius* is represented by fragments of stems, but is less abundant, and *Arthrostigma gracile* by some portions of stems. On the whole the assemblage is exactly those of the sandstone beds of the lower division of the Gaspé sandstones. There is nothing distinctively Upper Devonian in the collection.

The collection also contains two slabs of dark-coloured sandstone from Caithness, one of which contains what appears to be a fern stipe similar to those of the genus *Rhodea*. Another shows a remarkable plant having apparently a short stem giving origin to a quantity of crowded leaves which are long, narrow, and parallel-sided, and show only a very faint linear striation. This plant is identical both in the form and arrangement of the leaves with that found in the Devonian of Canada, and which I have named *Cordaites angustifolia*. I have, however, already stated in my Reports on the Flora of the Erian of Canada (Geological Survey of Canada, 1871 and 1882), that I do not consider this plant as closely related to the true Cordaites, and that I have not changed the generic name merely because I am still in doubt as to the actual affinities of the plant. Mr. Reid's specimens would rather tend to the belief that it was, as I have already suggested in the reports above cited, a Zostera-like plant growing in tufts at the bottom of water.

Some of the sandstone slabs from Murthly contain specimens of rounded objects referable to *Pachytheca* (Hooker), a genus of uncertain affinities but characteristic of Silurian and Lower Devonian beds on both sides of the Atlantic. One of these is perfectly spherical with a shining surface, and 2·75 mm. in diameter, the others have been broken so as to show a central cavity or nucleus about 1 mm. in diameter, and with a thick carbonaceous wall partly pyritised and showing obscure radiating fibres. Prof. Penhallow, of McGill University, has kindly examined these, and has compared them with slices of Pachytheca from the Wenlock limestone, kindly communicated by Mr. Barber, of Cambridge, and with specimens presented by Prof. Hicks from the Silurian of Corwen and with specimens in the author's collection from the Silurian of Cape Bon Ami; and also with the excellent figures in Mr. Barber's paper in the *Annals of Botany*. He has not been able, however, to arrive at any conclusions beyond the probable general similarity in structure of the various forms, which may, however, as Mr. Barber suggests, have differed in their nature and origin. The only thing certain at present seems to be that these puzzling organisms had a thicker outer coat of radiating fibres, and of so great density that it was less liable to compression than the other vegetable tissues with which it is associated.

A few small specimens sent more recently by Mr. Reid contain some curious but not very intelligible objects from the same beds. One is a stem coiled at the end very closely in a circinate manner. In form it resembles the circinate vernation of *Psilophyton princeps*, but is much larger. It may belong to *P. robustius*, or possibly to a fern, but is too obscure for certain determination. Several others appear to represent flattened fruits or sporangia of obovate form and of large size. One has a stalk attached with what seems a rudiment of a bract, and another shows obscure indications of having contained round or disk-shaped bodies about 2 mm. in diameter. All show minute longitudinal striation. I have not previously met with bodies of this kind in the Devonian, and can only suggest that they may represent the fructification of some unknown plant, possibly that to which Pachytheca belonged. J. WM. DAWSON.

Montreal, March 5.

Exact Thermometry.

I AM glad to observe that Prof. Sydney Young and myself are now in substantial agreement as regards the tension theory of the ascent of the zero in thermometers, and approximately in agreement as regards the actual cause of the ascent in the neighbourhood of the ordinary temperature.

Some time ago, in connection with an investigation of melting-point, I devoted three years to an examination of the properties of the mercurial thermometer. Among other conclusions which then seemed to me probable, the application of the known plasticity of glass under pressure to account for the enormous ascent (in lead-glass) of the zero at high temperatures appeared of some value. I have never advanced it as a mature theory, and am perfectly open to correction on the subject; but neither Prof. Crafts (with whom I at that time discussed the matter), nor any subsequent experimenter, has submitted the suggestion to a crucial examination.

Prof. Young's experiments (NATURE, March 27, p. 489) are very interesting as far as they go; but the kind of glass of which his thermometers are constructed is not that which brings out the peculiarities of the material in their most striking development. This, indeed, has long been known. It may well be that, in German soda-glass, the plasticity is masked by a preponderating tendency of the harder or more crystalline silicates of the bulb to set. Much could be done towards settling the question as to plasticity, if three thermometers of lead-glass—one vacuous,

one open to the air, and one with air sealed in—were heated together and successively to 100° C., 120°, 150°, 200°, 250°, 270°, and 300°, and the zeros observed. Even then, there still would remain to be explained the strange depression which I noticed in several sealed thermometers of lead-glass in the neighbourhood of 270°. At present, I regard the suggestion as neither proved nor disproved.

We are, in fact, only beginning to learn what silica and silicates are. I have quite lately, for example, found a critical point in the action of heat upon fire-clays, similar to the 270° point in the zeros (before referred to) of my lead-glass thermometers; and a similar point is known to exist in the relation of the refractive index of quartz to temperature. Results of this kind show clearly that thermometry is by no means an easy subject. Indeed, I might define it as a mixture of very complicated chemistry with very complicated physics.

Glasgow, March 28. EDMUND J. MILLS.

The Shuckburgh Scale and Kater Pendulum.

By permission of Prof. T. C. Mendenhall, Superintendent of the United States Coast and Geodetic Survey, and of Weights and Measures, I enclose to you for publication, if deemed suitable, a note relating to an abstract of a paper by General J. T. Walker, R.E., F.R.S., published in NATURE of February 20 (p. 381).

As the subject-matter refers to U.S.C. and G.S. Bulletin No. 9, I take the liberty of enclosing it also.

O. H. TITTMANN.

United States Coast and Geodetic Survey, Office of Weights and Measures, Washington, D.C., March 13.

Last summer the United States Coast and Geodetic Survey published an investigation, Bulletin No. 9, on the relation of the yard to the metre.

As the result of this investigation, values were deduced for the length of certain historic standards in England which differed very materially from the values previously assigned to them in metric measures.

Thus the length of the Royal Society's platinum metre, certified by Arago to be $17\cdot59\,\mu$ too short, was found to be only $7\,\mu$ too short.

This metre was compared by Captain Kater with a certain space (0–39·4 inches) on the Shuckburgh scale, and this space was in turn compared with his pendulum. It is therefore of interest to know whether the value deduced in the investigation referred to is accurate. It is the object of this note to call attention to a surprising verification of the deductions contained in Bulletin No. 9. Using the equation for the platinum metre found in that paper, namely—

$$\text{Platinum Metre} = 1\text{ m.} - 7\,\mu + 9\cdot126\,\mu,\ t\ \text{C}°,$$

we find

$$\text{at } 15°\cdot98\text{ C., P.M.} = 1 + 138\cdot8\,\mu;$$

but at this temperature Captain Kater found the space on the Shuckburgh scale

$$(0\text{–}39\cdot4\text{ inches}) = \text{P.M.} + 0\cdot02400\text{ inch, or } 0\cdot6096\text{ mm.,}$$

whence the space in question of the Shuckburgh scale $= 1\cdot007484$ m., and using for the coefficient expansion $18\cdot85 \times 10^{-6}$ for 1° C., we have at 16°·67

$$\text{the space} = 1\cdot0007614\text{ m.}$$

NATURE of February 20 (p. 381) publishes an abstract of a paper by General J. T. Walker, R.E., F.R.S., "On the Unit of Length of a Standard Scale by Sir George Shuckburgh, appertaining to the Royal Society," in which he states that the Shuckburgh scale was taken to Paris and compared with one of the standard bars of the International Bureau of Weights and Measures, by Commandant Defforges. The result of this comparison reduced to 16°·67 C., and as given by General Walker is

$$\text{the space} = 1\cdot0007619\text{ m.}$$

This agreement is perfect, more so, in fact, than the circumstances allow one to expect.

The agreement implies the correctness of the new values deduced in Bulletin No. 9 for the Ordnance metre and the platinum metre of the Royal Society, and gives the value of the metre as equal to 39·3699 inches as therein computed from Baily's and Sheepshank's comparisons, which established the relation between the Imperial yard and the space on the Shuckburgh scale.

It is to be noted that General Walker, ignoring Baily's and Sheepshank's comparisons, and adhering to the Clarke value 39·3704 + inches, deduces the (the writer of this thinks) erroneous conclusion, that the space on the Shuckburgh scale equals 39·400428 inches, the value according to their comparisons being 39·399896 inches. If to this value be added 0·04090 inch, the amount by which the distance between the knife-edges of the Kater pendulum exceeds the space 0–39·4 inches, the resulting length of the Kater pendulum at 16°·67 C. is 39·44080 inches, a value practically identical with that published by Kater, which is 39·44085 inches.

The Green Flash at Sunset.

THE explanation of the bluish (?) green flash of light sometimes seen at sunset given in your note last week (p. 495) does not seem to me to be a sufficient explanation of all the observations. If the phenomenon were due simply to refraction it would last for only a fraction of a second, and the colour would be much more blue than green. But, so far as my own observations go, the colour may last for several seconds, and is a bright pea-green, exactly similar to that shown by the sun many degrees above the horizon in South India in September 1883. To produce that green, as I have shown elsewhere, all that is required is the absorption due to a great thickness of vapour, combined with a certain amount of dust—water dust or other.

I saw a very pretty example of this last July when off the coast of Vancouver, B.C. The air was very moist and the rain-band correspondingly strong, while fine dust was supplied by the land breeze carrying with it particles from the burning forests inland. The sky was cloudless, but the haze was thick enough to allow one to look at the sun while it was still some degrees above the horizon, and the disk appeared of a brilliant golden-red, gradually changing to yellow, and, finally, while part was still above the horizon, it became a bright pea-green. The spectrum was similar to that figured in my paper on the green sun (R.S.E. Trans., xxxii. 389).

A few days later I had a view of the sunset from the Selkirks, where the air was very dry, the rain-band slight, but the haze considerable. The colours of the sun's disk were much less brilliant, and never passed beyond the stage of a reddish-copper tint.

C. MICHIE SMITH.

73 George Street, Edinburgh, March 31.

Foreign Substances attached to Crabs.

I MUST of course accept Prof. McIntosh's interpretation of his own statement, and admit that he has found *Molgula arenosa* frequently in the stomachs of Cod and Haddock. This Ascidian differs from the majority of its class in having allocryptic habits, but I have not yet made a sufficient number of experiments to be satisfied as to its edibility. It has also been a considerable difficulty to me that the extensive investigations of Brook and Ramsay Smith lend no support at all to the opinion that this Ascidian forms an article of food for ground-feeding fish. In any case the matter, though of much interest, is not one for discussion here, since *Molgula arenosa* is never one of the "foreign substances attached to crabs."

The statement made by Mr. Holt that "*Actinia mesembryanthemum* is a favourite food of the Cod," was so inconsistent with our knowledge of the habits and distribution of the two species that, as I expected, the grounds for his assertion prove to be entirely fallacious. My statement with regard to the offensiveness of Actinians to fishes was made after prolonged observation of the habits of the living animals and after experiment, while Mr. Holt bases his objection on the ground that the St. Andrews fishermen find *A. mesembryanthemum* to be a successful bait for Cod. One might as well argue that because bits of red flannel or of tobacco-pipe are highly successful baits in whiffing for Mackerel, therefore these substances form a "favourite food" of this fish. A moment's reflection also would have shown Mr. Holt that an Anemone impaled upon a fish-hook is a much less dangerous creature than one under natural conditions and with tentacles expanded.

During the past week an interesting observation of Eisig's has come under my notice which corroborates the view that the association between Crabs and Anemones is of primary importance for the protection of the Crabs. Eisig observed (see Journ. R.M.S., iii., 1883, p. 493) that an *Octopus* in its attacks upon a Hermit Crab would instantly retreat upon being touched by the stinging organs of the Actinian associated with it.

Plymouth, April 5. WALTER GARSTANG.

THE THAMES ESTUARY.

ALTHOUGH it is not practicable to say precisely where the river ends and the estuary commences, it will be sufficient for general purposes if the westward, or inner, boundary of the Thames estuary is assumed to be a line from Southend to Sheerness, the northern boundary as the coast of Essex, and the southern the coast of Kent; and it may be said to extend eastward to the meridian of the Kentish Knock light-vessel. The area inclosed between these lines is upwards of 800 square nautical miles, and the whole of the space is encumbered with banks, between which are the several channels leading to the river.

As the shores of Essex and Kent are low, and have no natural features by which they may be distinguished at a distance, and as a great part of the estuary is out of sight of land, even in the clear weather so rare in this country, it is evident that artificial marks in considerable number are required to make navigation at all practicable between the banks. In early times, when vessels were small and of light draught, few marks were necessary, but with increasing trade, necessitating vessels of heavy draught, new channels have to be marked farther from shore, and the demand for additional security to navigation has especially increased of late years, so that now there are no less than 3 lighthouses, 11 light-vessels, 8 gas buoys, 10 beacons, and 117 ordinary buoys marking the channels at present in use; and the demand for additional marks is likely to increase rather than diminish, for the deepest channels through the estuary have not yet been buoyed, and the changes in progress seem to favour the opinion that before many years some of them will have to be opened up to facilitate traffic.

In endeavouring to give an account of the changes in the channels of the estuary, it is difficult to obtain any authentic records earlier than the commencement of the present century. If such records exist, they are not at the Admiralty or Trinity House, the earliest surveys worthy of notice being those of Mackenzie, Graeme Spence, and Thomas, between 1790 and 1810; but no thorough investigation appears to have been taken up until Sir Francis Beaufort was Hydrographer, when, under his instructions, Captain Bullock surveyed the whole estuary between 1835 and 1845. Since then, Calver re-surveyed the whole of the southern part in 1862–63, and examined the northern banks in 1864, and lately the *Triton* has re-surveyed all the important channels and delineated the banks, and from these several surveys some idea can be obtained of the condition of the estuary at different epochs, and of the changes that are taking place.

These changes seem to be of two kinds; viz. permanent changes and periodic changes.

Before, however, describing the changes in progress, it will be well to give a general description of the estuary; and, to render the description more intelligible, three plans have been constructed, the first showing the whole estuary on a small scale with the tracks followed by vessels; the second being a diagram showing the state of an obstruction in a channel at different epochs, a characteristic permanent change; whilst the third plan shows the state of the Duke of Edinburgh Channel from the time of its first opening out to the present date, to illustrate what seems to be a channel opening and closing periodically.

It is worthy of notice that all the banks of the estuary are of sand intermixed with shells; even the foreshore consists mostly of sand, between high and low water marks; in two places only is it of shingle (viz. off Whitstable and at Garrison Point, Sheerness); and in a few places, near the entrance of the rivers discharging into the estuary, there is a little mud, whilst in the vicinity of Margate there are some ledges of chalk. The sand is very fine, and although, when dry, it possesses a tolerably hard surface, directly it begins to be covered it is all alive. When beacons are erected on any of the banks, or a ship gets on shore, the tidal streams scour out the sand in the immediate neighbourhood, and cause the wrecks to sink and finally disappear. Although without actual boring it is not possible to give the exact depth of these sands, it is probable that they are upwards of 60 feet thick, for channels of that depth have opened out across the sands and again closed up, so that the bank has been dry at low water where 60 feet formerly existed; and the Goodwin Sands, in the Downs, which have been bored, proved to be 80 feet in thickness. All the banks, and the channels between them, trend in a north-east and south-west direction: this is doubtless due to the fact that the stream outside the estuary is running to the northward whilst the tide is ebbing from the river, and, consequently, the ebb stream in the estuary is deflected to the north-eastward.

The channels into the estuary, therefore, must be classed under two headings: (*a*) those which follow the main line of the flood and ebb streams, and (*b*) those which do not follow the general stream of the tide.

In the former category are the Warp, West Swin, Middle Deep, East Swin, Barrow Deep, Oaze Deep, and Black Deep; in the latter are the Middle Swin, Queen's Channel, Prince's Channel, Alexandra Channel, Duke of Edinburgh Channel, Gore Channel, &c., which are all more or less of the nature of swatchways across the main line of the sand-banks of the estuary. In the Black and Barrow Deeps, which are the deepest and straightest channels through the estuary, the ebb stream runs 7 hours and the flood 5 hours, and the ebb is much stronger than the flood, the stream setting fairly through. In the Duke of Edinburgh Channel, the deepest swatchway of the estuary, the streams at the north and south ends are of a rotatory character, revolving with the hands of the clock.

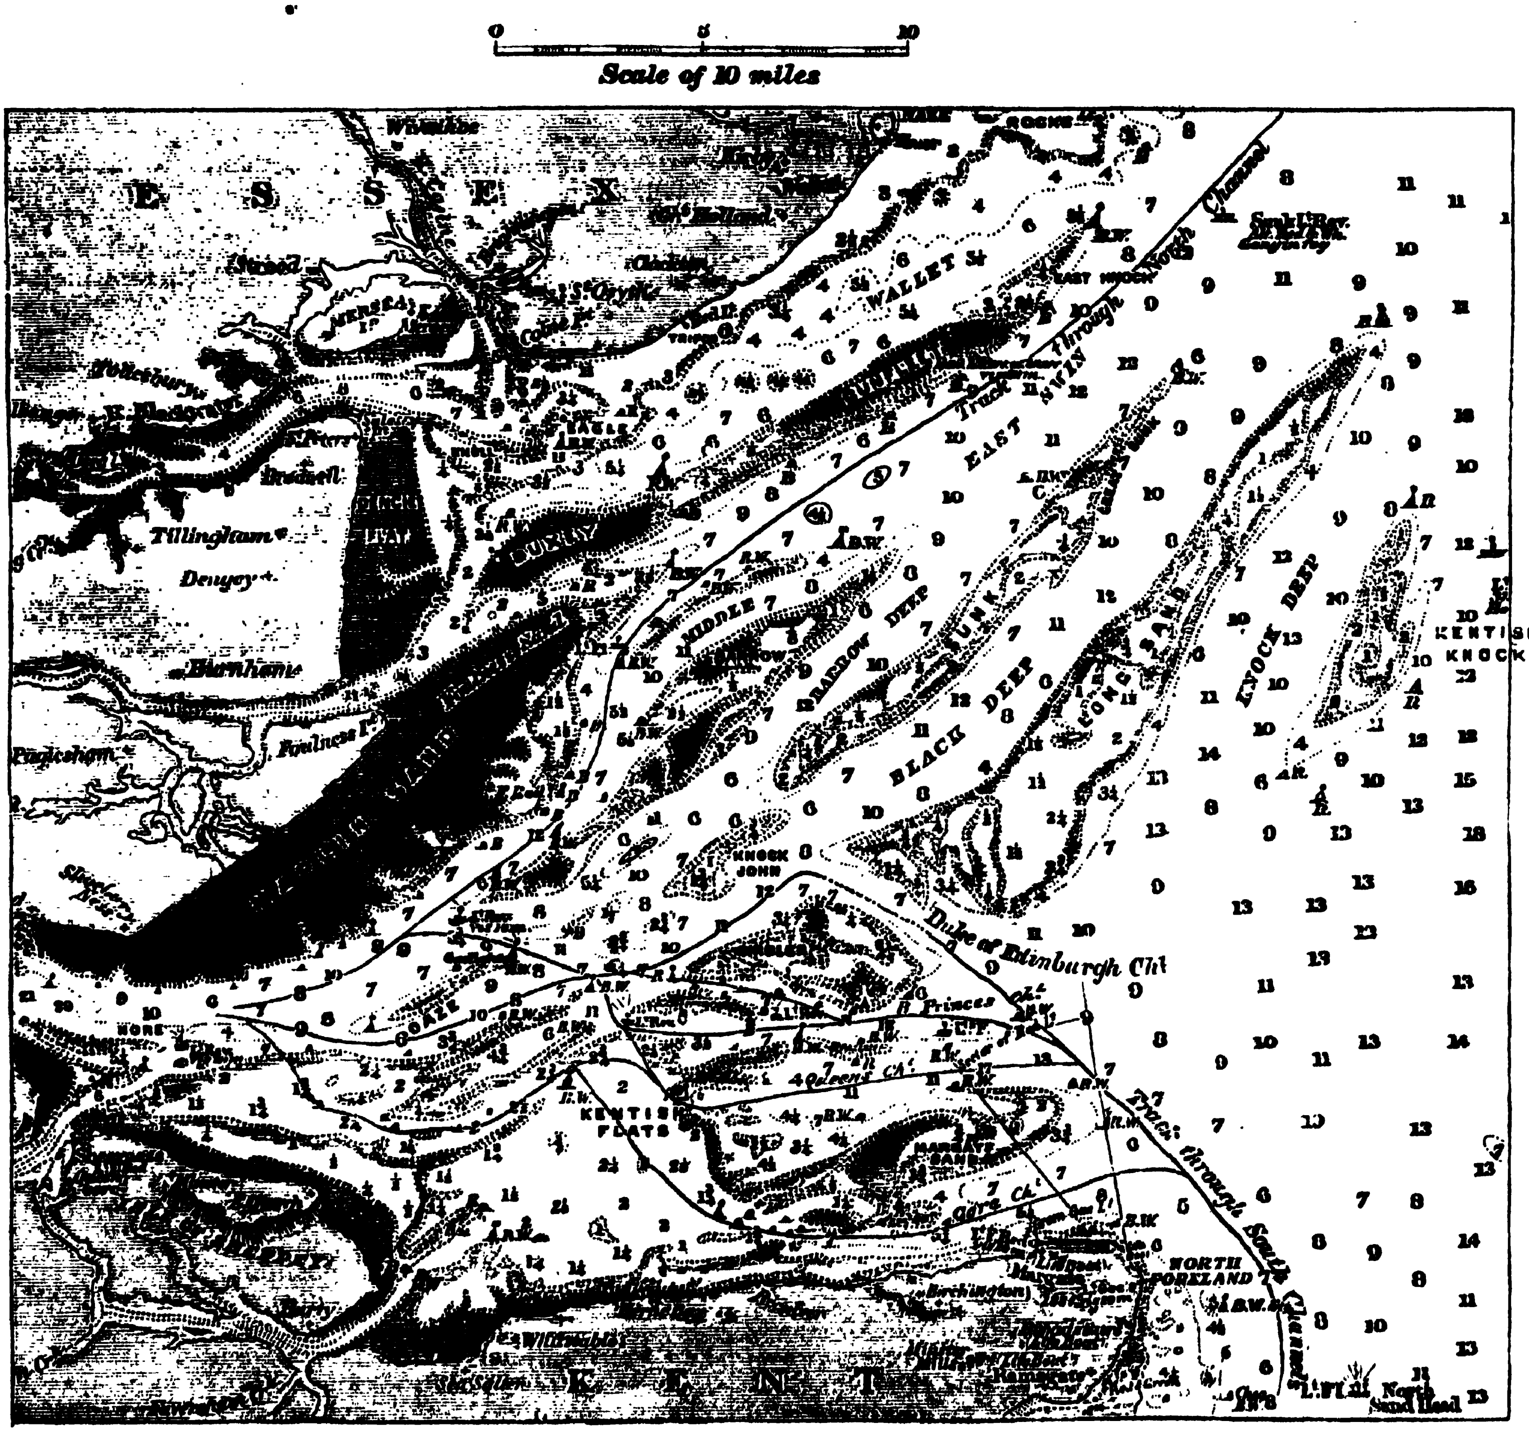
I would here explain that in a large space like the Thames estuary the difficulty of buoying the various channels increases very considerably with their distance from the shore. With permanent marks erected on the shore, it is easy to place buoys in selected positions, not far from land, in fairly clear weather. But when the distance from the shore has increased so that the marks erected on the land cannot be seen, we have either to erect other marks on the sand-banks and carry out a triangulation, or we are dependent on floating bodies (fixed by land objects) to fix other floating bodies farther off. That this is an eminently unsatisfactory method will be evident when it is stated that each time the Kentish Knock light-vessel has been satisfactorily fixed, the position has been very different from that supposed. When fixed by Calver in 1864, she was found to be one mile N.E. ½ N. of her charted position; and when fixed by the *Triton* last year, she was found to be one mile and a half S.E. by E. of her supposed position.

The errors probably creep in somewhat in the following way. Something goes wrong with the light-vessel after she has been satisfactorily fixed: a collision takes place, the fog-siren gets out of order, or one of the many things happens which necessitates the vessel being taken into port. A temporary light-vessel is substituted, and she is anchored in almost precisely the same position as the other, but probably before her mushroom bites the ground it has dragged somewhat. By the time the other vessel is repaired and brought out, the temporary one may be a cable or so away from the original position. As the weather is usually thick, the permanent vessel has to be anchored as nearly as practicable in the position of the temporary craft, and her mushroom may drag somewhat before biting the ground, &c. Thus a series of errors creep in without there being adequate means of checking the position of the light-vessel, and within the last few years the *Triton* has found the Leman and Ower light-vessel one mile away from her charted position, the

Dudgeon light-vessel about one mile from her supposed position, and the Outer Downing light-vessel nearly two miles from the charted position.

All these light-vessels are either out of sight of land, or can only be seen from an elevated position on the shore on rare occasions.

It is therefore naturally the object of the Elder Brethren of the Trinity House to utilize the channels closest to the shore, and, as these channels are also the most direct into the Thames, the northern channel following the general trend of the Essex coast, and the southern that of the Kentish coast, no other channels would require marking if the depth in these was sufficient for the traffic. Hitherto the one northern channel has been enough, but this is steadily shoaling, as will be described further on; but the southern channels are mostly shoal, and one after another has had to be opened up as the size of the vessels and their draught of water increased, until there are now five buoyed channels off the Kentish coast, two of which are lit; but only one can be termed a deep-water channel,



PLAN I.—THAMES ESTUARY. (Depths in Fathoms.)

and this would seem to be the very channel which opens and closes periodically, as will be shown subsequently. Should this prove to be the case, there will be intervals during which there will be no deep-water channel into the river on the south side of the estuary.

By a reference to Plan I., showing, on a small scale, the whole estuary, it will be seen that the northernmost channel, viz. that close to the coast of Essex, is named the Wallet, and that this is separated by a series of banks, termed Buxey and Gunfleet, from the channel next it. These banks, which are collectively 18 miles long, are dry for the most part at low water; there are, however, two narrow passages across them, one separating the Buxey from the Gunfleet, called the Spitway, and the other separating the Buxey from the Dengie flat (extending from the Essex coast). The Spitway, which, when sounded in 1800, had a depth of nine feet, has remained at that depth until recently, but now has only a depth of 5 feet at low water; the channel between the Buxey sand and Dengie flat has about 12 feet, and is merely an

outlet for the River Crouch. It will therefore be seen that the Wallet is really only a channel to the Rivers Colne, Blackwater, and Crouch, and is of no importance as a channel towards the Thames. It was last surveyed by Staff-Captain Parsons in 1877, and as its features have not materially changed since 1800, it will probably not be surveyed again for many years, unless the swatchways across the Gunfleet should deepen or others open up of sufficient importance to render the Wallet useful as a traffic channel. There were formerly other swatchways across the Gunfleet, but these are now closed.

The channel next the Wallet is named the King's Channel, or Swin; the eastern part is named East Swin; the central part Middle Swin, and the inner part West Swin. This is the channel through which all the traffic between London and the northern ports of the Kingdom passes, and it is almost always crowded with shipping. The East Swin is bounded at first by the Gunfleet sand to the north-westward and the Sunk sand to the south-eastward, and is 3 miles wide; but 8 miles within its entrance two other banks commence—one, the Barrow, being very extensive, upwards of 13 miles in length and 2 in breadth; and the other, the Middle or Hook sand, a narrow ridge about 6 miles long, extending along the north-west face of the Barrow sand, and leaving a channel nowhere less than $\frac{3}{8}$ of a mile wide between them. It will thus be seen that 8 miles within the entrance of the East Swin it is split up into 3 channels; the northernmost retaining the same name, the channel between the Middle, or Hook sand, and the Barrow being known as the Middle Deep, whilst the channel between the Barrow and Sunk sands is known as the Barrow Deep. The Middle Deep rejoins the Middle Swin, but the Barrow Deep and West Swin both run into what is known as the Warp. The Swin is well buoyed and lighted throughout, but the Middle and Barrow Deeps have not yet been buoyed. In fact, it has hitherto not been necessary to do so, as the least water in the main channel of the Swin has, up to recently, been ample for all that has been required; but a steady shoaling has been taking place in a critical part of this channel since 1800, and it now seems to be only a question of time before the Middle Deep will have to be marked.

To illustrate the changes in progress here, Plan II. has been constructed, showing the condition of the critical part of the navigation in the Swin each time it has been thoroughly surveyed. By this diagram it will be seen that in 1800 the ruling depth in the channel between Foulness sand and the Middle or Hook sand was 35 feet at low water. Forty-three years later, a bar, on which the depth at low water was 28 feet, had formed between the Foulness sand and the Middle. In 1864 the depth had decreased to 24 feet, and, in 1889, to 21 feet, showing a steady decrease since 1800 of about one foot in every six years. The deposit is of sand, shells, and mud. This is the only shallow part of the Swin; and as it is evident that, so far as our knowledge extends, we may expect it to continue to decrease in depth, and as even now, with strong south-west winds prevailing in the North Sea, it is by no means rare for the tide to fall 3 feet below the level of low water ordinary springs, so that the depth would be reduced to 18 feet, it is clear that vessels of heavy draught will either have to wait for tide or use another channel. Already our small armoured vessels of war have to time themselves to reach this obstruction by half-tide. Fortunately, the Middle Deep is an alternative channel with ample depth in it, which only requires to be buoyed, and this can readily be done. This Deep seems to be in a better condition now than it has been for 50 years, for, when surveyed by Bullock, in 1843, there was a bar of 25 feet at its east end. This had disappeared when it was surveyed by Calver in 1864, and there was then a channel of two cables in width between the edges of the 30 feet contour lines of soundings surrounding the Middle sand and Barrow. There is now a channel four cables in width between those contour lines in the narrowest part of the Deep.

The Barrow Deep, referred to as the third channel branching away from the East Swin, is deep throughout, and without obstruction. It varies somewhat, as shown by the different surveys, but is an excellent highway, which only requires buoying to be available for traffic. At present the London County Council are allowed to empty rubbish in this Deep, which seems rather a pity, as there is no knowing what may be the result eventually, more especially as we have at present no observations to show to what depth the tidal scour is of service. Any interference with the channels, likely to cause an obstruction, should be avoided.

The Sunk sand, which is the south-eastern boundary of the Barrow Deep and the north-western boundary of the Black Deep, has undergone great alterations since originally surveyed in 1800. In that year it is shown as a long sand which really extended from the present north-east end in one continuous line of shallow water to the inner end of the Oaze sand, a distance of 26 miles. On it were many dry patches, named Great Sunk, Little Sunk, Middle Sunk, Knock John, &c., and the only passage across was a three-fathoms channel at low water at the eastern end of the Oaze. When surveyed by Bullock, 1835-45, this chain of sands had altered very considerably, and had several channels or swatchways across it —a swatchway of 22 feet at low water between the Great and Little Sunk sands: a swatchway of 60 feet at low water between the South-West Sunk and the Knock John sands; a 35-feet channel 1½ mile wide between the Knock John and North Knob sands; and a swatchway of 26 feet between the North Knob and the Oaze. When surveyed by Calver, 1862-64, this series of banks had again altered: the swatchway between the Great and Little Sunk sands had only 12 feet in it at low water; the swatchway between the South-West Sunk and the Knock John had shoaled to 40 feet; but the channel between the Knock John and North Knob had deepened to 45 feet, and a narrow channel of 40 feet at low water had opened out between the Oaze and North Knob.

In 1888-89, when surveyed by the *Triton*, the swatchway between the Great and Little Sunk sands had entirely disappeared; the swatchway between the South-West Sunk and the Knock John sands had narrowed and shoaled to 29 feet; the channel between the Knock John and North Knob shoals had decreased to 24 feet, whilst the channel between the North Knob and the Oaze had increased its width to one mile, with about the same depth (viz. 40 feet) at low water. In fact, the chain of sands known as the Sunk, Knock John, Knob, and Oaze, which were, in 1800, one continuous bank, after breaking up into separate patches, again show signs of resuming the form they possessed when originally surveyed, the only deep channel across them now being between the Oaze and North Knob.

The Black Deep is the channel bounded to the north-westward by the chain of sands just described, and to the south-eastward by another chain of sands named Long Sand: Shingles, Girdler, and the flats extending from the Kentish shore. It is a deep-water channel, the inner part of which has been buoyed since 1882, and lighted since December last, as it communicates by a deep-water swatchway, named the Duke of Edinburgh Channel, with the deep water off the North Foreland, and so forms a convenient outlet for the heavy-draught vessels bound southward from the Thames. There seems to be some tendency to shoal in the north-east end of the Black Deep, but it has only once been sounded—viz. by Bullock, in 1843; and we have not yet quite completed our examination of it throughout, so that no thorough comparison is yet practicable.

the Black Deep formerly extended in one continuous line from the Kentish coast to the Long Sand Head, a distance of over 30 miles. Across this chain of sands there have always been shallow swatchways which communicated by somewhat circuitous channels with the deep water of the estuary. These are now 5 in number: (1) the Gore Channel, which passes close to Margate and then across the Kentish flats; (2) the Queen's Channel, which, passing between the Margate sand and Tongue sand, also leads across the Kentish flats; (3) the Prince's Channel, which leads between the Tongue sand on the south side, and the Shingles and Girdler sands on the north side, into the Black Deep; (4) the Alexandra Channel, which leads from the Prince's Channel to the Black Deep; and (5) the Duke of Edinburgh Channel, which leads from the deep water of the North Sea into the Black Deep. All these channels are buoyed. In the Gore Channel (sometimes called the South Channel), which has been in use from early times, the depth at low water is 10 feet. The shallow grounds shift backwards and forwards, but there seems to have been always as little as 10 feet at low water in some parts of this channel. In the Queen's Channel, which was buoyed in the last century, the least depth in passing over the Kentish flats is 13 to 14 feet at low water. In Prince's Channel, which was buoyed in 1846, and lighted in 1848, the least depth is 20 feet at low water, but there is a patch of 17 feet at its western end in the centre of the channel which seems to be always in this channel though not always in the same position. It is shown by Bullock in 1839, by Calver in 1862, and by the *Triton* in 1880. The Alexandra Channel, which is a swatchway between the Shingles and Girdler sands, had no existence in 1800, the Girdler and Shingles forming with the Long Sand a continuous chain at that date. In Bullock's survey of 1839, the Alexandra is shown as a blind inlet on the north side of the Prince's Channel, which was cut off from the Black Deep by a ridge over which the depth was 7 feet at low water. When surveyed by Calver in 1862, the least depth in the channel was 20 feet; and when surveyed by the *Triton* in 1888, the least depth was 23 feet. It is, however, much narrower now than in 1862, and if it continues to decrease in width will not be available for traffic, as there is not now much more than room for two large vessels to pass each other, and bad steerage might cause an accident.

Of the Duke of Edinburgh Channel, which is a broad swatchway at present dividing the Long Sand from the Shingles Sand, we have a tolerably complete history; and as this would seem to be a channel which opens and closes periodically, Plan III. has been constructed to show its condition each time it has been surveyed. The first record we have of it is on an old chart of 1794, when it is shown as a 9-feet swatchway, and is named "Smugglers' swatch." When surveyed by Thomas, in 1810, it was named "Thomas's New Channel," and there was then a narrow passage carrying 30 feet at low water between the Long Sand and Shingles. In 1839, when surveyed by Bullock, and named "Bullock Channel," this 30-feet swatchway of Thomas's was obstructed by a bank in the middle, which dried at its north end, leaving a passage of 15 feet on its east side, and a very narrow gat of 25 feet on its west side, but one mile farther west a new channel was opening out, the shoalest water in which was 16 feet. This appears as an inlet into the sand-bank on Thomas's chart.

The next time it was surveyed was by Calver, in 1862, at which date Thomas's Channel had closed completely, but the channel west of it had opened out and become a wide deep-water swatchway, the least depth in which was 42 feet at low water. Early in 1882 it was thought advisable to buoy this channel, and the *Triton* was ordered to examine it, when a 30-feet patch was discovered near its centre. In the autumn of 1887, this patch was reported to have shoaled; and in 1888, when examined again by the *Triton*, it was found to be upwards of a mile in length with 22 feet on it. In October 1889, the channel was again examined, when the least depth on the central patch was found to be 21 feet, and it had a tendency to shallow to the eastward. The channel was buoyed in the summer of 1882, and re-named by the Elder Brethren of the Trinity House "Duke of Edinburgh," after the Master of the Trinity House. It was lighted in December 1[illegible]

The various surveys seem to show that the estuary has a tendency for the most part to return to the condition it was in about 1800. In that year there were no deep-water swatchways across the banks, and the channels that opened up subsequently seem now to be all closing again. At any rate, those in use as ship channels evidently will require constant watching.

Should the Duke of Edinburgh Channel close, and none other open out, it will materially interfere with the heavy traffic into the estuary from the southward, for it will necessitate either waiting for high water or passing round outside into the Black or Barrow Deeps, which will have to be buoyed and lighted to make them readily accessible.

There is one other shoal, the "Kentish Knock," which may be said to belong to the estuary. This is a sand-bank about 6 miles in length and 2 in breadth, on the south-east side of the outer part of the Long Sand. Its shape and area, within the contour-line of five fathoms, would appear to be fairly constant; but it had a swatchway across the north end, when surveyed by Calver in 1864, which has now entirely disappeared. Between the Kentish Knock and Long Sands is a channel, two miles wide, named the Knock Deep. At the north end of this channel the soundings are much shoaler than when surveyed by Bullock. In some cases the difference is as much as 12 feet.

Although the general tendency of the banks in the estuary seems to be to revert to the condition they were in about the year 1800, it is not possible to predict that this will certainly be the case. If, as seems probable, the condition of the estuary is due to the action of the sea in casting up banks, and of the tidal flow in cutting channels through the banks thus formed, it is evident that much will depend on prevailing types of gales. There can, however, hardly be a doubt that any diminution of the volume of the water running into and out of the estuary would diminish its power of making deep-water channels, so that any action tending to decrease the flow into and out of the various rivers should be avoided if possible; as although it is conceivable that a given type of strong winds, extending over a lengthened period, might have the effect of closing the various swatchways across the banks, it does not follow that a cessation of these winds would cause the channels to be again opened out if the volume of the tidal flow was seriously diminished. T. H. TIZARD.

NOTES.

THE respect in which science is held in France was once more exhibited in a very striking way at Saint Sulpice, Paris, on Tuesday, in connection with the funeral service of M. Hébert, Professor of Geology, member of the Institute, and honorary *doyen* of the Faculty of Sciences. Deputations from the Institute and Faculty of Sciences were present, and the Paris correspondent of the *Times* says that all the great scientific and literary institutions of Paris were represented. At the cemetery of Montparnasse, where the interment took place, speeches were delivered by M. Gaudry, in the name of the Institute; M. Darboux, in the name of the Faculty of Sciences; M. Marcel Bertrand, in the name of the Geological Society; M. Jannery, in the name of the Normal School; and M. Bergeron, in the name of the old pupils of M. Hébert.

GERMAN papers announce the death of Dr. Karl Jacob Loewig, Professor of Chemistry at the University of Breslau, Director of the Chemical Laboratory, and author of many eminent works on chemistry. He was born at Kreuznach on March 17, 1803, and died at Breslau on March 27.

THE "Inspectors' Instructions" relating to the Code of 1890 have been issued this year with remarkable promptitude. The document is one of great importance, and it is satisfactory that all who are interested in popular education will have ample time to study it before the various questions connected with the new Code are discussed in Parliament.

THIS week the National Union of Teachers has been holding its 21st Annual Conference at the Merchant Taylors' School, London. The meetings began on Monday, when the President, Mr. H. J. Walter, delivered his inaugural address. Speaking of the new Code, Mr. Walter said the teachers of the country would accept and welcome it; and although they reserved their right to criticize the details freely, and unhesitatingly to state that in many points the Code was capable of improvement, "they would work loyally with the Education Department in the endeavour to show such an improvement in the education of the country that the public would be ready to listen with attention and respect when teachers made suggestions for further changes and advance in the same direction."

M. GASTON BONNIER has been elected President of the Botanical Society of France for the year 1890, and MM. E. Roze, A. Michel, J. Poisson, and J. Vallot, Vice-Presidents.

THE International Exhibition of Geographical, Commercial, and Industrial Botany, proposed to be held at Antwerp, has been postponed till next year.

AN International Exhibition of Horticulture, which will be largely of a scientific character, will be held in Berlin from April 25 to May 5.

AN Electro-technical Exhibition is to be held at Frankfort-on-the-Main next year. It will be divided into twelve sections.

SOME exhibits in the Science Department (under the direction of the Rev. Dr. West and Mr. C. Carus-Wilson) of the Bournemouth Industrial and Loan Exhibition, opened on the 7th inst., are worthy of special notice. Among these are a collection of British and foreign oysters lent by the Poole Oyster-fishing Company, and a collection of birds' eggs, for which Mr. R. G. H. Gray has received a special prize. The first prize has been awarded to Mr. E. H. V. Davies, who exhibits an interesting collection of recent and fossil local shells. The various stages in the process of developing photographs are illustrated in a series exhibited by Mr. Jones. In the Geological Section, large specimens of fluor-spar have been lent by Dr. West, who also contributes a collection of Eocene fossils from the London, Hampshire, and Paris basins. Mr. C. Carus-Wilson shows a case of remarkably well-preserved fossils of various geological ages, including a gigantic shark's tooth (*Carcharodon*) from Rio; also, garnets in quartz, and samples of musical sands. Leaves from the Bournemouth Beds are well represented by Mr. Bennett's collection. In the Entomological Section, Mr. McRae's collection of British Lepidoptera attracts much attention; the Rhopalocera and Macro-Heterocera are nearly all represented a large number having been bred by Mr. McRae from larvæ obtained in or near Bournemouth. A special prize has been awarded to Mr. Harding for a large astronomical telescope constructed entirely by himself. The Exhibition will close on the 21st inst., when the prizes will be distributed by the Duchess of Albany.

THE Royal Microscopical Society will hold its first evening *soirée* in its new rooms, 20 Hanover Square, on Wednesday, April 30, at 8 p.m.

M. LECLERC DU SABLON has been appointed to a Professorship of Botany at Toulouse, and is succeeded in his post of assistant naturalist to the chair of Organography and Vegetable Physiology at the Museum of Natural History at Paris, by M. Morot.

DR. LUDWIG KLEIN has been appointed Professor of Botany in the University of Freiburg-in-Breisgau.

M. PAUL MAURY has been attached to the Geographical Exploring Commission of the Mexican Republic in the capacity of botanist, and is about to depart for Mexico on a botanical expedition.

THE plans of the Danish expedition to the east coast of Greenland are now complete. Lieut. Ryder will command a party of nine, and during next summer, as soon as the ice permits, they will go by steamer to the east coast, and then devote two years to the investigation of the district between lat. N. 66° and 73°. At the end of that time they will be fetched by the steamer from Denmark.

THE French Society "Scientia" informs its members that its next dinner, on April 30, will be presided over by M. C. Richet and by M. de Lacaze-Duthiers, in whose honour the dinner is to be given. The last dinner was given in honour of Francis Darwin.

AT the general monthly meeting of the Royal Institution, on April 7, the special thanks of the members were returned for the following donations to the fund for the promotion of experimental research: Mr. Ludwig Mond, £100; Mr. Lachlan M. Rate, £50.

AT the Royal Institution the Hon. George C. Brodrick will begin a course of three lectures, on the place of Oxford University in English history, on Tuesday (April 15); Prof. C. V. Boys will begin a course of three lectures, on the heat of the moon and stars, on Thursday (April 17); and Captain Abney will begin a course of three lectures, on colour and its chemical action, on Saturday (April 19). The evening meetings will be resumed on Friday (April 18), when Sir Frederick Bramwell will give a discourse on welding by electricity.

THE Marlborough College Natural History Society, according to its latest Report, is in a most flourishing condition. The year 1889 was for the Society "one of continued prosperity and progress." On April 9, 1889, the Society completed its twenty-fifth year, and the members afterwards commemorated the occasion by an excursion to Stonehenge.

DR. VON DANCKELMAN has contributed to *Mittheilungen aus den deutschen Schutzgebieten*, vol. iii., an important paper on the climate of German Togoland, and of the neighbouring districts of the Gold and Slave Coasts. The observations are drawn from all available sources, from those first made by Dr. Isert at the then Danish settlements in 1783–85, down to the most recent observations by English, French, and German observers. A good deal of information exists, comparatively speaking, from this part of West Africa, and among the best of the observations are those made in 1888–89 by the German officials at Bismarckburg (lat. 8° 12′ N., long. 0° 34′ E.), at an altitude of about 2330 feet above the sea. A comparison of the tables given for the various colonies shows that the highest air pressure occurs in July and August, and the lowest in February and March. The monthly range is small, amounting to less than 0·2 inch. Temperature varies considerably with the position relatively to the coast. While at Akassa, on the coast, the mean daily range is only about 10°, at Bismarckburg it is double that amount. And during the hot season the range is double what it is in the cool season. Rainfall also varies with position relatively to the coast. The rainy seasons are March to June,

and September to November. Dr. von Danckelman gives valuable statistics about the harmattan, which is generally understood to be a cold wind. He shows, however, that during the periods of this wind the temperature both in the morning and evening is warmer than on other days, and that the mean daily temperature is nearly 2° warmer. The air on these occasions is so dry that the hygrometric tables are not low enough for the reduction of the observations. On one occasion the relative humidity was only 9 per cent., with a temperature of 94°.

We have received from Mr. D. Dewar his "Weather and Tidal Forecasts for 1890." The author has previously published similar forecasts for past years, and they are said to be mainly based upon the simple idea that the prevailing westerly movement of the air in the two great belts in the north and south temperate zones is due to the continued westerly (west to east) movement of the sun and the moon, and it is claimed that the probable weather, while referring generally to the northern hemisphere, is chiefly applicable to the British Isles and neighbourhood. We have made a rough comparison of the forecasts with the actual weather experienced in the British Isles during the first three months of this year. The weather predicted by Mr. Dewar for January largely consists of cold and anticyclones, whilst the actual weather experienced was conspicuous for the absence of cold, with the exception of the first two or three days, and its mildness probably exceeded that of any January during the last half-century. At Greenwich the thermometer did not once fall below the freezing-point after the 3rd. Considering February as a whole, the forecasts were rather more successful. In March, the early part of the month was to have been mild, except in the north. The first few days were colder than in any March during the last half-century, except in the north, where milder weather was experienced. The weather predicted for the remainder of the month consists almost wholly of cold and snow, whereas the weather was exceptionally mild, and the Greenwich temperature on the 28th has only twice been exceeded in March during the last fifty years.

In the current number of the *Zoologist* it is stated that a wealthy Berlin manufacturer has a shooting near Luckenwald, where the Wapiti, *Cervus canadensis*, has been acclimatised. Between January 20, 1889, and January 20, 1890, seven of these animals were shot there, one of them having a head of fourteen points.

Dr. W. King, Director of the Geological Survey of India, has commenced, in the current number of the Records of the Survey, the publication of the provincial index of the minerals of India, which is intended as a help towards the compilation of an annual statement showing the quantities and value of mineral products in British India, for the publication of the mining and mineral statistics of the Empire. Dr. King's classification is of a broad and popular nature. The provinces or Presidencies and Native States are taken in alphabetical order, and the mineral products of each are set down with notes as to the quantity, quality, and output. The mineral products themselves are divided into "Important Minerals," "Miscellaneous Minerals," "Gem Stones," and "Quarry Stones." Under the first head are included only coal, iron ores, gold, petroleum, and salt. Under the second head come metallic ores, borax, gypsum, asbestos, soapstone, sulphur, and the like. "Gems" include amber, beryl, diamond, garnet, jade and jadeite; while clays, limestones, marbles, kunkar, slate, &c., are grouped as quarry stones. The first instalment of the list ends with the Central Provinces. This index may help to dispel the common idea that India is rich in minerals. The greater part of the entries are mere indications of the reported existence of ores, while those which note a regular production of any commercial importance are few and far between.

In one of the Bombay Natural History Society's papers, Mr. G. Carstensen, Superintendent of the Victoria Gardens, Bombay, makes a bold suggestion for facilitating the study of botany in India. His experience, he says, has taught him that the study of botany is far more popular in the northern countries of the European Continent than in British possessions, and he cannot help thinking that this fact may be clearly attributed to the difference in the botanical terminology. While the terms used in English works on botany are too frequently quite unintelligible for the layman, because they are in most cases Anglicized Latin words, the terms used by German and Danish authors are generally easily comprehended, because they are translated into the mother language, refer to objects of daily life, or are derived from the language itself. He therefore proposes that the Botanical Committee of the Bombay Society be requested to revise the existing terminology, and to substitute English and intelligible terms for the more unintelligible ones. He gives a few examples of the English substitutes he proposes. The natural arrangement of plants consists of two large divisions, Phanerogams, or "flower-plants," and Cryptogamous plants, or "spore-plants." "Flower-plants" are again divided into Dicotyledons, or "two-seed-leaved." The "two-seed-leaved" in the way are divided into Angiosperms, or "seed-vessel-plants," and Gymnosperms, or "naked-seeded plants," and so on. For the "natural orders" he would substitute existing or new English names, and for "genera" he would substitute "forms." In a complete flower the calyx would become the "cup," the sepals "cup-leaves," the corolla the "crown," the petals "crown leaves;" the cup and crown together, now known as the perianth, would be the "floral cover," and so on through the andræcium and gynæcium, and the whole anatomy of the plant. The adoption of this method would, Mr. Carstensen thinks, "vastly increase the number of students of botany, and in the end would materially further the progress of this unfortunately neglected science."

The subject of dreams seems to demand more thorough study than it has yet received from science. An American, Dr. Julius Nelson, of New York, has lately published the results of an examination he made of some 4000 of his dreams. He finds that the dreams of evening generally follow great physical or mental fatigue, and are associated with the events of the day. The same applies to night dreams, which, however, have more of a terrifying element in them. The most remarkable and pleasant are the morning dreams, occurring after complete rest of the brain. Fancy then appears to have its widest range and activity, working marvellous transformations, and giving clear vision of the past and the future. Dr. Nelson further finds that the vividness of his dreams is subject to regular fluctuations of 28 days, and that they also vary with the seasons, so that they are very vivid in December, and least vivid in March and April. An old popular superstition attaches special importance to dreams in the twelve nights from Christmas to January 6, and it is suggested that this is perhaps because dreams at that time have been found very vivid and distinct.

The skin of Arctic voyagers, after the long night of winter, often appears pale, with a tinge of yellowish-green, on return of sunlight. The nature of this phenomenon, was, at the instance of Prof. Holmgren, studied by Dr. Gyllencreutz, in the expedition of 1882–83, and the results are given in a German physiological journal. Holmgren pointed out that the phenomenon might be subjective, due to a change in colour-sense through the long darkness; or objective, due to changes in pigment of the blood; or both. An examination of the colour-sense of the men before and after the polar night revealed no

change in this. The blood was examined by measuring the position of absorption bands of hæmoglobin with a given thickness of layer, and estimating their darkness. No change in the quality of hæmoglobin was detected, but the quantity, in some individuals, judging by changes in the width and darkness of the bands, was lessened towards the end of winter. Holmgren suggested, as an *experimentum crucis* with regard to the question of a subjective or objective cause, that someone should exclude himself from sunlight a month longer than the others: and to this infliction the engineer Andrée submitted. When he left his prison, his skin had a greyish-yellow tint. The conclusion arrived at is that the change of skin is due to an anæmic-chlorotic condition, possibly that of incipient scurvy.

We have received Tylar's "Photographic Calendar" for the year 1890. It comprises, among other advantages, practical hints selected from the best contributors, and various reproductions of several of the pictures that gained prizes in the competition held last year. There is also an extended list of the author's specialities, as well as those of other dealers; and throughout there is a variety of useful information handy for reference. The prize list is more varied and comprehensive than that given last year.

The "Photographers' Diary and Desk-book" for the year 1890, which is issued by the proprietors of the *Camera*, is a very handy and useful volume. Developing and other formulæ are printed in large type, capable of being read in the dim light of the dark room. A series of dark-room procedures has been added, including the work of developing the negative, silver printing and toning, platinotype printing (cold, hot, and sepia processes), Blanchard's platinum black process, and bromide printing. A selection of the most important and useful of the recent improvements in photographic apparatus is given, with several illustrations, preceded by some particulars of the objects of the Photographic Convention of Great Britain, with a list of its officers. The diary portion, interleaved throughout with blotting-paper, gives ample space for the daily record of photographic work.

The Royal Horticultural Society has issued the first part of vol. i. of its Journal. This part includes reports of the Vegetable Conference held at Chiswick on September 24, 25, and 26, 1889, and of the Chrysanthemum Conference held at Chiswick on November 5 and 6, 1889.

The Transactions of the Congrès Colonial and the Congrès d'Hygiène et de Démographie, held in Paris last summer, have been issued. The Transactions of the latter Congress cover over 1200 octavo pages, and include many really useful papers.

Michel Troja was one of the first surgeons who experimented (1775) on the regeneration of bone. His book, "De Ossium Regeneratione," has just been published, for the first time, in French.

The last Annual Report of the Dutch Colonies in the East Indies contains references to several subjects of scientific interest. The military surveys were carried out on the west coast of Sumatra and in Dutch Borneo. In the former a large area was mapped on a scale of 1 : 20,000, and in Borneo a flying survey of 1 : 200,000 was made over a considerable district. Triangulation and cartographical work were continued in Sumatra; various maps were finished in Batavia; and the parts of the great map of Netherlands India, including the Residencies of Madura and Pasuruan, were put in hand at the Hague. The members of the Hydrographic Department were busy on the coasts of Java and Madura; an astronomical station was established on the Sunda Islands; and the study of the languages of the archipelago was continued by gentlemen appointed for the purpose—Balin, Javanese, Old Javanese, Macassar, Bugin, &c. There are 182 meteorological stations in working order, 100 in Java and Madura, 34 in Sumatra, 6 in Billiton and Banka, 9 in Borneo, 17 in Celebes, 2 in Bali, and the remainder at other points in the archipelago. Of scientific expeditions of various kinds a long list is given. These include geological investigations in Sumatra and Flores, botanical on Key Islands, ethnological in the Balta region of Sumatra, ethnological, botanical, and zoological, on the east coast of Borneo. An arrangement has been made, by which in each year one student from home will be able to spend some months in the famous Buitenzorg Botanical Gardens.

Another paper by Drs. Curtius and Jay upon hydrazine, N_2H_4, describing a new and very simple method of obtaining this recently isolated base from the ammonia addition compound of aldehyde, $CH_3 . C\begin{matrix} \diagup H \\ -OH \\ \diagdown NH_2 \end{matrix}$, is communicated to the latest number of the *Berichte*. The first step consists in acting with sodium nitrite upon a cold slightly acidified aqueous solution of aldehyde-ammonia, by which a nitroso-compound of the composition $C_5H_{11}O_2 . C\begin{matrix} \diagup H \\ \diagdown N.NO \end{matrix}$ is formed. The reaction probably completes itself on the lines of the following equation—

$$3CH_3 . C\begin{matrix} \diagup H \\ -OH \\ \diagdown NH_2 \end{matrix} + NO . OH = C_5H_{11}O_2 . C\begin{matrix} \diagup H \\ \diagdown N-NO \end{matrix} + 2H_2O + 2NH_3.$$

About 300 grams of aldehyde ammonia are dissolved in a little ice-cold water, and neutralized with cold dilute sulphuric acid. About 40 c.c. more of the dilute acid are then added, and afterwards a concentrated solution of 70 grams sodium nitrite in iced water. The liquid at once becomes turbid owing to separation of minute yellow globules of the nitroso-compound, termed nitroso-paraldimine, on account of its derivation from paraldehyde, the triple polymer of common aldehyde. This nitroso-paraldimine is a lemon-yellow liquid possessing an intense camphor-like odour. Its molecular weight has been determined by Hofmann's density method, and found to correspond with the formula above quoted. It decomposes at its boiling-point, but may be readily distilled in steam or *in vacuo* without suffering change. The imine itself, corresponding to the nitroso-compound, has also been isolated. The hydrochloride, $C_5H_{11}O_2 . C\begin{matrix} \diagup H \\ \diagdown NH . HCl \end{matrix}$, is obtained when moist hydrochloric acid gas is passed through an ethereal solution of nitroso-paraldimine, in the form of a mass of white needles. From this hydrochloride the free base, paraldimine, $C_5H_{11}O_2 . C\begin{matrix} \diagup H \\ \diagdown NH \end{matrix}$, may be obtained by treating its ether solution with silver oxide. Paraldimine is a clear colourless liquid of a sharp odour resembling that of paraldehyde. It solidifies to white crystals in a freezing mixture. It boils almost without change at 140° C., but polymerizes to a white solid on standing in a sealed tube for some weeks. Water or alcohol decompose it into paraldehyde and ammonia. Its hydrochloride, which is readily formed from the base with great evolution of heat by leading dry hydrochloric acid gas over the pure liquid, may be converted into the nitroso-compound by treating with a strong solution of sodium nitrite. The nitroso-compound itself, on reduction with zinc dust and dilute sulphuric acid, at once yields hydrazine sulphate, $N_2H_4 . H_2SO_4$. The course of the reaction is better seen when the gentler reducing mixture, zinc dust and glacial acetic acid, is allowed to act upon an ethereal solution of nitroso-paraldimine. An amide termed amidoparaldimine, $C_5H_{11}O_2 . C\begin{matrix} \diagup H \\ \diagdown N . NH_2 \end{matrix}$, is then first formed, and may be

isolated as a strongly basic volatile liquid, which yields a very hygroscopic hydrochloride with hydrochloric acid. On boiling this hydrochloride with dilute sulphuric acid, it is decomposed, with assimilation of the elements of water, into paraldehyde and hydrazine—

$$C_6H_{11}O_2 \,.\, C\begin{matrix}\diagup H \\ \diagdown\!\diagdown N \,.\, NH_2\end{matrix} + H_2O = C_5H_{11}O_2 \,.\, C\begin{matrix}\diagup H \\ \diagdown\!\diagdown O\end{matrix} + N_2H_4.$$

The hydrate of hydrazine is readily obtained from the sulphate by simple distillation with alkalies.

THE additions to the Zoological Society's Gardens during the past week include an Egyptian Cat (*Felis chaus*) from North Africa, presented by Mrs. Florence J. Waghorn; a Stoat (*Mustela erminea* ♂), British, presented by Mr. Cuthbert Johnson; two Mantchurian Cranes (*Grus viridirostris*) from Corea, presented by Mr. Campbell; three Long-eared Owls (*Asio otus*), British, presented by Mr. W. Geoffrey N. Powell; a Black-faced Weaver-Bird (*Hyphantornis* sp. inc.), from South Africa, presented by Commander W. M. Latham, R.N., F.Z.S.; a Three-toed Sand Skink (*Seps tridactylus*), European, presented by Mr. J. C. Warburg; two Hybrid Deer (between *Cervus elaphus* ♂ and *Cervus sika* ♀), deposited; a Diana Monkey (*Cercopithecus diana* ♀) from West Africa, eight Undulated Grass Parrakeets (*Melopsittacus undulatus*) from Australia, purchased; a Rhesus Monkey (*Macacus rhesus*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

OBJECTS FOR THE SPECTROSCOPE.

Sidereal Time at Greenwich at 10 p.m. on April 10 11h. 16m. 18s.

Name.	Mag.	Colour.	R.A. 1890.	Decl. 1890.
			h. m. s.	° ′
(1) G.C. 2386	—	—	11 15 47	+ 3 50
(2) 72 Leonis	5	Yellowish-red.	11 9 22	+23 42
(3) υ Leonis	4	Yellowish-white.	11 31 18	− 0 13
(4) δ Leonis...	2	White.	11 8 18	+21 8
(5) 152 Schj.	5	Red.	12 39 58	+46 3
(6) R Hydræ	Var.	Very red.	13 23 43	−22 43

Remarks.

(1) The General Catalogue description of this nebula is as follows: "Bright, pretty large, round, pretty suddenly much brighter in the middle." In 1869, Prof. Winlock observed the spectrum at Harvard College Observatory, and stated that it was continuous, with a possible bright line near λ 525. The nebula does not appear to have been spectroscopically examined by any other observer, so that further observations are required to confirm this result. If there really be a bright line as recorded, others may certainly be expected. Comparisons with the carbon flutings in the Bunsen or spirit-lamp flame spectrum should be made. It seems highly probable that many of the so-called "continuous" spectra of nebulæ really consist of bright lines or flutings superposed upon a continuous spectrum, as Dr. Huggins has stated that brighter parts have been suspected in some cases, and I myself have often noted irregularities, notably in the Great Nebula of Andromeda. In 1866 Dr. Huggins was careful to point out that his use of the term "continuous" was not to be understood to mean more than that, when the slit was made as narrow as the feeble light permitted, the spectrum was not resolved into bright lines.

(2) This star has a very fine spectrum of Group II. According to Dunér, the bands 2–8 are wide and dark, especially those in the red. This indicates, as I have pointed out on previous occasions, that the star is probably considerably advanced towards Group III., in which the bands will be replaced by lines. It will be interesting to know if any lines exist in the spectrum of the star at present, and, if so, what lines they are.

(3) A star of the solar type (Konkoly). The usual differential observations are required.

(4) A star of Group IV. (Gothard). Usual observations required.

(5) It is generally agreed that 152 Schj. is one of the finest examples of stars of Group VI. It shows the usual bands of carbon very strongly marked, and all of the secondary bands are well visible. We have certainly still a great deal to learn about stars of this group, and the present favourable position of a typical example may therefore be taken advantage of for further inquiry.

(6) At the last maximum of this interesting variable, Mr. Espin found that the F line was bright in its spectrum, the general spectrum being a very fine one of Group II. Mr. Espin also noted that the bright bands (probably the bright flutings of carbon) were relatively brighter as the star was on the increase, and weaker when its luminosity was decreasing. It is very important that a recurrence of these phenomena at the approaching maximum of April 11 should not escape observation, even though the star is not one which rises early in the evening at this time of the year. The period of the variable is about 434 days, but is apparently decreasing. In 1708 it was about 500 days. It varies from magnitude 4–5 at maximum to about 10 at minimum.

A. FOWLER.

THE APEX OF THE SUN'S WAY.—A determination of the amount and direction of solar motion is given by Mr. Lewis Boss in *Astronomical Journal* No. 213. This determination is an important one, because of the fact that, out of the 253 stellar motions used, only 49 are known to have been previously employed in a similar research, and it is by means of new material and variations of arrangements in its use that any general facts or laws are likely to be discovered. The stars whose proper motions have been utilized were given in No. 200 of the above journal, and are all contained in the Albany zone, which is 4° 20′ in breadth, and at a mean declination of 3° north of the celestial equator.

The method employed is substantially that proposed by Airy, and in the first solution five stars having proper motion greater than 100″ in a century were excluded, with the following results:—

	Mean magnitude.	Proper motion per century.	Maximum angular value of the solar motion for 100 years as viewed from the unit of distance.	R.A. of the apex of solar motion.	Decl. of the apex of solar motion.
		″	″	°	°
First series (135 stars)	6·6	21·9	12·39	280·4	+ 42·8
Second series (144 stars)	8·6	20·9	13·73	285·7	+ 45·1
Both series combined	7·6	21·4	13·09	283·3	+ 44·1
Probable errors	—	—	± 1·00	± 6·9	± 3·2

When stars are excluded whose proper motions per century amounted to 40″ or more, the following are the resulting values:—

		″	″	°	
Single series (253 stars)	7·7	17·80	10·58	288·7	+ 51·5
Probable errors	—	—	± 0·60	± 7·2	± 3·2

The values of the several elements of solar motion, as determined by Struve and Bischof, are as follows:—

		″	″	°	°
Struve	6·0	8·00	4·36	273·3	+ 27·3
Bischof	7·5	47·58	33·67	290·8	+ 43·5
„ (using Argelander's method)			—	285·7	+ 48·5

By using the present declinations of the American ephemeris, Mr. Boss finds that the value given by Struve for the declination of the sun's way requires a correction of + 10°·4, thus making it + 37°·7, which is more in accordance with the other values given above.

The most probable co-ordinates of solar motion might therefore be assumed to be—

R.A. = 280°; Decl. = + 40°.

STABILITY OF THE RINGS OF SATURN.—The *Bulletin Astronomique* for February 1890 contains an interesting paper by M. O. Callandreau, on the calculations of the late Clerk-Maxwell, relative to the movement of a rigid ring around Saturn. It is well known that Laplace found it impossible for a homogeneous and uniform ring surrounding a planet to be in a state of stable equilibrium, and remarked that irregularities must exist in the

form of the ring, which, in combination with a slight eccentricity, secured its stability. Maxwell found that the irregularities of a ring possessing a permanent movement ought to be very sensible, and that the appearance of the rings of Saturn was incompatible with that required by his demonstration. He considered the case of a planet occupying the centre of the ring, whereas Laplace's hypothesis required a slight eccentricity. This question was not, however, treated separately, and M. Callandreau has subjected it to mathematical analysis. First, taking the case of a symmetrical ring when the centre of gravity will be on a symmetrical axis, and then the case required by Laplace, viz. that the centre of gravity is not exactly coincident with the geometrical centre, the author shows that the conditions stated by Laplace are not sufficient to ensure stability.

BROOKS'S COMET (*a* 1890).—This comet was observed at Paris on March 28 and 30. It was seen as a round nebulosity, about 40″ or 50″ in diameter, with a very pronounced central condensation, and was about the tenth magnitude.

BRIGHT LINES IN STELLAR SPECTRA.—The Rev. J. E. Espin reports the discovery of bright lines in the spectrum of θ_1 as well as in that of θ_2 Orionis, and possibly in that of S Coronæ as well.

ON THE DEFORMATION OF AN ELASTIC SHELL.[1]

THIS paper treats of the deformation of an elastic shell whose radii of curvature are everywhere great in comparison with the thickness, which is supposed uniform. The subject has been dealt with in a very able manner by Mr. A. E. H. Love in a recent paper (Phil. Trans., 1888), but it seemed desirable, on various grounds, that it should be attacked from an independent point of view. The method here followed is that explained in a former communication, "On the Flexure of an Elastic Plate" (December 1889). The results, as regards the general theory, are closely analogous with those of Mr. Love, and a comparison of the two investigations gives a physical interpretation to the various groups of terms which enter into his equations. There are some differences of detail, arising from a slight difference in the quantities chosen to express the flexural strains, but they are not practically important.

The great difficulty of the present subject, as contrasted with the theory for a plane plate, is, that we cannot draw an absolute line of demarcation between the deformations in which the cardinal feature is the extension of the middle surface, and those which involve flexure with little or no extension. This appears to arise mainly from the fact pointed out by Mr. Love, that it is in general impossible to satisfy the boundary conditions by a deformation in which the middle surface is absolutely unextended. But, this being admitted, the question remains in any specific problem, as to the amount and distribution of the extension, and, in particular, whether there are any modes of deformation (or of free vibration) in which, after all, it plays only a subordinate part. Mr. Love answers this question in the negative, in opposition to the views advocated by Lord Rayleigh in two well-known papers. In the present communication Mr. Love's argument is examined, and it is pointed out that cases may occur in which the extensions (though comparable with the flexural strains) may be confined to so small a region of the shell (near the edges) that their contribution to the total energy of deformation is insignificant.

In order to bring the matter to an issue in a definite instance, I have chosen the case of a cylindrical plate (such as a boiler-plate) bent by a proper application of force over its straight edges, so that the strained form remains a surface of revolution, the circular edges being free. The analytical work in this case is very simple, and the physical meaning of the various terms which occur is easily recognized. In the interpretation of the result it appears that a good deal turns upon the ratio which the breadth of the plate (in the direction of the generating lines) bears to a mean proportional between the radius and the thickness. If this ratio is large, the bending forces may be practically replaced by two equal and opposite couples uniformly distributed over the straight edges, and having these edges as axes. The strained form is almost accurately cylindrical; near the circular edges we have extensions of the same order as the flexural strains, but these rapidly die out (at the same time fluctuating in sign) as we press inwards, and the anticipation that their total energy would be small compared with that due to flexure is confirmed. In such a case, then, the approximate methods used by Lord Rayleigh, in which no account is taken of the conditions at a free edge, are fully justified. But if, keeping the radius and the thickness constant, we diminish the breadth of the plate until it is comparable with the mean proportional aforesaid, we get a sort of transition case between a plate and a bar, which cannot be satisfactorily treated except on the basis of the general equations. Finally, when the breadth becomes small in comparison with the mean proportional, the plate behaves like a curved bar, and an approximate treatment is again applicable.

In an appendix I have worked out, from the general equations of elasticity, the uniform flexure of an infinitely long cylindrical plate; this being, at present, the only case of flexure in which it appears easy to carry out the solution (on these lines) to a full interpretation.

[1] Abstract of a Paper read by Prof. Horace Lamb, F.R.S., before the Mathematical Society on January 9.

SCIENTIFIC SERIALS.

Timehri, being the Journal of the Royal Agricultural and Commercial Society of British Guiana (printed at the Argosy Press, Demerara, vol. iii., part ii., new series).—This interesting *brochure* contains matter of general interest, as well as information which might be expected in an agricultural and commercial journal. Specialization cannot be pushed to its extreme limits in a colony, and a Society of this nature naturally admits matter into its Journal which are not strictly either agricultural or commercial. Thus the papers on primitive games and on the wild flowers of Georgetown must be regarded, respectively, as of ethnological and purely botanical interest, but, nevertheless, occupy a great part of the number, especially if we leave out of consideration the reports of meetings and other official matter connected with the working of the Society. Fruit-growing in the Gulf States of America, Caracas as a place of resort, and a short paper on some scale insects inimical to vegetation are the principal topics of a distinctly economic value. The paper entitled the "Letters of Aristodemus and Sincerus" is a review of an old book published in 1785-88 in twelve volumes, dealing with the colonies of Demerara and Essequibo, and are therefore of great interest to the present population. In 1785 the colonies had just been given over by the French, who held them on behalf of the Dutch for about three years. No town existed up to that date in Demerara, but during the French occupation a little village had grown up in the neighbourhood of Brandwagt, which they called *la nouvelle ville*, or Longchamps. The fort on the east bank of the Demerara River (now called Fort William Frederick) was also built at the time, and named Le Dauphin, while another on the opposite side was called La Raine. From such historical, social, scientific, and economic materials a most interesting although somewhat diffusive number has been produced, showing evidence of mental activity and high culture, pleasant to see far away from the main centres of civilization. The style of the writing, the printing, and the illustrations are all of a high class. How far the London publisher, Mr. E. Stanford, of Cockspur Street, is responsible for the excellent "get up" of the volume we are unable to even conjecture; but we trust we may be permitted to say, without offence, that the number of *Timehri* before us is highly creditable to the literary talent and tastes of British Guiana.

Quarterly Journal of Microscopical Science, February.—On the anatomy of the Madreporia; V., by Dr. G. Herbert Fowler (plate xxviii.). Gives an account of the anatomy of *Duncania barbadensis*, *Galaxea esperi*, *Heteropsammia multilobata*, and *Bathyactis symmetrica*, and gives a figure of the typical structure of the genus Madrepora.—Contributions to the anatomy of earthworms, with descriptions of some new species, by Frank E. Beddard (plates xxix. and xxx.). This paper gives an account of the structure of three new species of Acanthodrilus, with remarks on other species of the genus. The new species are *A. antarcticus*, *A. rosa*, and *A. dalei*. Further remarks on the reproductive organs of Eudrilus, with special reference to the continuity of ovary and oviduct.—On the certain points in the anatomy of Perichæta, with description of *Perichæta intermedia*, n.sp.—On the phagocytes of the alimentary canal, by Armand Ruffer (plate xxxi.). Concludes that the wandering cells of the lymphoid tissues of the alimentary canal have the power of proceeding to the free surfaces of such tissues, and of taking into their interior

lower micro-organisms and foreign matter (charcoal, &c.): there are both macro- and microphages; these are stages, the larger can swallow the smaller and digest them.—Notes on the hydroid phase of *Limnocodium sowerbyi*, by Dr. G. Herbert Fowler (plate xxxii.), records observations made during May 1888; neither medusoid or hydroid appeared in 1889; two hydroids and a budding medusoid are figured.—Note on certain terminal organs resembling touch corpuscles or end bulbs in intramuscular connective tissue of the skate, by Dr. G. C. Purvis (plate xxxiii.).—Note on the transformation of ciliated into stratified squamous epithelium as the result of the application of friction, by Drs. J. B. Haycroft and E. W. Carlier (plate xxxiii.).—On the development of the ear and accessory organs in the common frog, by Francis Villy (plates xxxiv. and xxxv.).—On *Thelaceros rhizophoræ*, n.g. et sp., an Actinian from Celebes, by P. C. Mitchell (plate xxxvi.). The Actinian here described was obtained by Dr. Hickson in a mangrove swamp in Celebes, by the side of one of the roots of a Rhizophora; the tentacles have compound hollow protuberances round the margins of the oral surface, with numerous small simple or compound hollow protuberances (rudimentary accessory tentacles) in radial lines on the oral disk.—Notes on the genus Monstrilla, Dana, by Gilbert C. Bourne (plate xxxvii.). Gives details of all the known species of this aberrant genus of Copepods.—On the maturation of the ovum, and the early stages in the development of Allopora, by Dr. Sydney J. Hickson (plate xxxviii.). Gives a general summary of events; the formation and fate of the trophodisc, the changes of the germinal vesicle, the formation of the embryonic ectoderm the history of the yolk, and general considerations.

SOCIETIES AND ACADEMIES

LONDON.

Royal Society, March 27.—"The Variability of the Temperature of the British Isles, 1869-83 inclusive." By Robert H. Scott, F.R.S.

The material discussed has been the daily mean temperature derived from twenty-four hourly measurements of the thermograms at the seven British observatories during the period of their continuance, 1869–83.

The differences between the successive daily means have been extracted, irrespective of sign, and these values averaged monthly.

To the figures for the 7 observatories certain values have been added from Dr. Hann's paper in the *Sitzungsberichte* of the Vienna Academy for 1875 for Makerstoun and Oxford, the only British stations in Hann's list, and for Vienna, St. Petersburg, and Barnaul, as instances of Continental climates, as well as for Georgetown, Demerara, as an instance for a tropical station.

The figures for the 7 stations are much lower than those for Makerstoun and Oxford, probably owing to the fact that the means used in the two latter cases were not twenty-four hourly, nor for as many as fifteen years.

The highest variability on the mean of the year is at Kew (2°·7). Then follow Armagh, Glasgow, and Stonyhurst (2°·5), Aberdeen (2°·4), and Falmouth and Valencia (1°·9). The greatest absolute monthly value is 5°·4 for Glasgow, November 1880; the least, 0°·7, for Valencia, July 1879.

The mean values for each month are given.

The question of whether great changes are more frequently positive or negative has been investigated. Mr. Blanford states ("Climate of India") that in India (Calcutta and Lahore) sudden falls of temperature are more frequent and greater than sudden rises.

A preliminary inquiry showed that it was not interesting to investigate all changes, as the numbers showing + and − signs respectively were nearly equal.

The changes above 5° in the twenty-four hours were all examined, and the result showed that in these islands sudden rises of large amount are more frequent and more extensive in amount than sudden falls—the reverse to what obtains in India.

One instance of a rise of 23°·8 at Aberdeen, December 16, 1882, was the greatest recorded, and this disturbance was confined to the east of Scotland.

The figures were then examined for frequency. The values were arranged, irrespective of sign, according to their magnitude, in six subdivisions:—0-0°·9, 1·0-4°·9, 5·0-9°·9, 10·0-14°·9, 15·0-19°·9, 20·0-24°·9, and the totals divided by 15. The first two intervals taken together are equal to one of the others, but, as by far the greater number of the changes fell below 5°·0, it seemed well to see how many fell below 1°·0.

The range of changes is least at Falmouth and Valencia. In all cases the mean number of changes between 1°·0 and 4°·9 exceeds half the number of days in the month.

The daily mean values have also all been examined, with the view of discovering their distribution on the thermometer scale.

Seven columns were taken, covering the space from 10° to 80°, of 10° each, excepting that the space from 20° to 40° was not divided equally.

In 1881, Stonyhurst had four days in January with a mean below 20°, and nineteen days in which the mean temperature was below 32°. At Aberdeen and Glasgow the cold was not so intense. Neither at Falmouth nor Valencia did the mean temperature ever fall below 20°. The hottest station is Kew. In the fifteen years it shows in all thirty-five days with a mean above 70°.

The figures were then divided by 15, to obtain frequency, as before, and the results shown. They are also shown graphically in a plate, but there all the curves do not appear. Those for Valencia and Falmouth agree almost exactly, except in July and August. Those for Armagh, Glasgow, and Stonyhurst are so close to each other, that one curve is taken to represent all.

Royal Microscopical Society, March 19.—Prof. Urban Pritchard, Vice-President, in the chair.—A letter from the President, regretting his inability to attend in consequence of a fall, was read.—Mr. J. Mayall, Jun., read a letter from Prof. E. Abbe, of Jena, announcing the donation of one of Zeiss's new apochromatic $\frac{1}{10}$ objectives of 1·6 N.A. He also sent a condenser of 1·6 N.A., and a flint glass slide containing mixed diatoms mounted by Dr. H. van Heurck, of Antwerp, together with a supply of flint glass slips and cover-glasses for use in mounting objects for examination with the new objective. It was of course understood that in order to exhibit the full power of the increased aperture it was necessary to employ a condenser of corresponding aperture, and the objects to be viewed must be mounted on slips with covers, and mounting and immersion fluids of correspondingly high refractive power. In order to further test this lens, a committee has been appointed. Mr. Mayall called attention to and described two microscopes by MM. Nachet and Pellin, of Paris, which were exhibited by Mr. Crisp.—Mr. Rousselet exhibited a number of Rotifers to show their abundance at this season of the year.—A specimen sent by Colonel O'Hara, supposed to be some kind of entozoon which had been passed in urine, was exhibited.—Prof. Bell gave a *résumé* of Mr. A. D. Michael's paper on the variations of the female reproductive organs, especially the vestibule, in different species of *Uropoda*, the author being unavoidably absent through illness.—Mr. C. H. Wright exhibited and described specimens of a new British Hymenolichen, *Cyconema interruptum*.—Mr. E. M. Nelson read a short note on the images of external objects produced from the markings of *P. formosum*.—A note was read from Dr. H. van Heurck correcting an error in his recent communication to the Society relating to the structure of diatoms.—Mr. Mayall read a translation of an article by Prof. E. Abbe on the use of fluorite for optical purposes, in which it appeared that the special qualities of the new apochromatic lenses were due to the employment of this mineral in their construction.—Mr. C. H. Gill read a paper on some methods of preparing diatoms so as to exhibit clearly the nature of the workings, which was illustrated by numerous photomicrographs.—Mr. P. Braham exhibited and described a new form of oxyhydrogen lamp adapted for microscopical purposes, the lamp being so mounted as to be used in any position above or below the object. Its application to photomicrography was demonstrated in the room.—Mr. Clarkson also exhibited one of the same lamps separate from the photomicrographic arrangement.—The next *conversazione* was announced to take place on April 30.

Zoological Society, March 18.—Prof. W. H. Flower, F.R.S., President, in the chair.—The Secretary exhibited (on behalf of the Rev. G. H. R. Fisk) a specimen of a White Bat, obtained at Somerset West, near Cape Town, believed to be an albino variety of *Vesperus capensis*.—Captain Percy Armitage exhibited and made remarks on two heads of the Panolia Deer (*Cervus eldi*), obtained on the Sittang River, Burmah. One of

these was of an abnormal form.—Mr. Sclater exhibited (on behalf of Mr. Robert B. White) examples of four species of Mammals, obtained in the Upper Magdalena Valley, in the department of Tolima, U.S. of Colombia.—Dr. Mivart, F.R.S., read a paper on the South-American Canidæ. The author called attention to the difficulties in the way of the correct discrimination of these animals, and to what appeared to him to be the unsatisfactory character of some of Burmeister's determinations and descriptions. Forms to which the names *fulvipes*, *griseus*, *patagonicus*, *entrerianus*, *gracilis*, *vetulus*, and *fulvicaudus* had been assigned were declared to be quite insufficiently discriminated from *Canis azaræ*. On the other hand, two very marked varieties, or possibly species, were noted and distinguished under the appellations *Canis parvidens* and *Canis urostictus*, the type of each of which was in the British Museum, both the skin and the skull extracted from it in each case.—Mr. R. I. Pocock read a revision of the genera of Scorpions of the family *Buthidæ*, and gave descriptions of some new South African species of this family.—Mr. F. E. Beddard read a paper on some points in the anatomy of the Condor (*Sarcorhamphus gryphus*).—A communication was read from Prof. R. Collett, containing the description of a new Monkey from North-East Sumatra, proposed to be called *Semnopithecus thomasi*.

Geological Society, March 26.—J. W. Hulke, F.R.S., Vice-President, in the chair.—The following communications were read:—On a new species of *Cyphaspis* from the Carboniferous rocks of Yorkshire, by Miss Coignou, Cambridge. Communicated by Prof. T. McK. Hughes, F.R.S.—On composite spherulites in obsidian from hot springs, near Little Lake California, by Frank Rutley, Lecturer on Mineralogy in the Royal School of Mines. The spherulites which form the subject of the present communication have been previously noticed, and it was then suggested that a smaller spherulitic structure was set up in the large spherules after their formation. In the present paper evidence was adduced in favour of a different mode of origin. It was argued that the small spherulitic bodies (primitive spherulites) were developed in the obsidian before it assumed a condition of rigidity, and that they floated towards certain points in the still viscid lava, and segregated in more or less spherical groups, though there is no evidence to show what determined their movements; furthermore, that from a point or points situated at or near the centre of each group, crystallization was set up, giving rise to a radiating fibrous structure, which gradually developed zone after zone of divergent fibres until the entire mass of primitive spherulites was permeated by this secondary structure—a structure engendering a molecular rearrangement of the mass, such as would obliterate any trace of structure which the primitive spherulites might have originally possessed. In a supplementary note the views of Mr. J. P. Iddings with reference to the spherulites in question were given. Mr. Iddings considers that the structures here described as primary are of secondary origin. The author stated in detail his reasons for adhering to the conclusions given in this paper. The Chairman said that the sequence of the different portions brought forward with so much care by the author is one which admits of much discussion. Rev. E. Hill said that the explanation of the divergence of these crystallizations was extremely interesting. As to which structure came first, it is difficult to determine. In the section exhibited under the microscope he agreed with Mr. Rutley as to the sequence. The question of molecular motion after consolidation in igneous rocks is a subject of great importance.—A monograph of the Bryozoa (Polyzoa) of the Hunstanton Red-Chalk, by George Robert Vine. Communicated by Prof. P. Martin Duncan, F.R.S.—Evidence furnished by the Quaternary glacial-epoch morainic deposits of Pennsylvania, U.S.A., for a similar mode of formation of the Permian breccias of Leicestershire and South Derbyshire, by William S. Gresley.

PARIS.

Academy of Sciences, March 31.—M. Hermite in the chair.—M. de Jonquières, having presented a memoir containing the complete text and review of a posthumous work of Descartes, "De Solidorum Elementis," with a translation and commentary of the work, addressed a note giving some brief explanations of the matter contained in it. In communications made on February 10 and 17, the author endeavoured to show that Descartes knew and applied the relation between the faces, apices, and edges of a polyhedron, known as Euler's formula, and expressed as $F + S = A + 2$. The present communication seems to put the matter beyond doubt.—M. P. Schutzenberger, in reply to criticisms of M. Berthelot, adduces experiments pointing to the conclusion that the condensation of carbonic oxide by the silent discharge cannot be effected without the presence of water.—Some further remarks on the preceding communication, and on the desiccation of gases, by M. Berthelot. The author still holds the opinion that the water shown by M. Schutzenberger to be present in his condensed carbonic oxide may have passed through the glass tube under the action of the electric discharge.—A new method for the microscopical study of warm-blooded animals at their physiological temperatures has been devised by M. L. Ranvier, and consists of placing the microscope and the preparation under examination in a bath of warm water (36° C. to 39° C.).—Deformities of the feet and toes following phlebitis of inferior members; phlebitic club-feet, by M. Verneuil.—Observations of Brooks's new comet (*a* 1890), made at the Paris Observatory, by M. G. Bigourdan.—Observations of the same comet, made with the great equatorial of Bordeaux, by MM. Rayet and L. Picart.—Observations and elements of the new minor planet (289) discovered at the Nice Observatory on March 10, by M. Charlois.—On the position of the sun-spot of March 4, by M. Spœrer.—On the graphic statics of elastic arcs, by M. Bertrand de Fontviolant.—Theoretical and experimental researches on Ruhmkorff's coil, by M. R. Colley. The author has investigated the current which results from the superposition of two currents—one non-periodic, diminishing according to the law of an exponential curve; the other periodic, and with progressively decreasing amplitude.—On the conductivities of the phenols and of oxybenzoic acids, by M. Daniel Berthelot. In this important paper the author gives the results of an examination of the three oxybenzoic acids by means of their electrical conductivities, and a research into the way they behave in the presence of one, two, or three molecules of soda. These acids having both phenol and acid functions, the conductivities of alkaline phenates were first determined.—The laws of annealing, and their consequences from the point of view of the mechanical properties of metals, by M. André Le Chatelier. These laws have been studied by heating metallic wires, hardened by a series of passages through a draw plate, to different temperatures and during different periods of time.—On the indices of refraction of salt-solutions, by M. B. Walter.—Action of hyposulphite of soda on silver salts, by M. J. Fogh. The amount of heat disengaged during the action of hyposulphite of silver upon various silver salts has been investigated.—M. V. Marcano, from his anthropological researches at Venezuela, gives evidence of the existence of metallurgy in South America previous to Columbus.—Influence of the chemical constitution of compounds of carbon upon the sense and variation of their rotary power, by M. Philippe A. Guye.—On the preparation and some of the properties of fluoroform, by M. Meslans. The density of the gas obtained is 2·44, and it is found to liquefy at 20° under a pressure of 40 atmospheres.—On some thiophenols derived from ordinary camphor, by M. P. Cazeneuve.—On the stranding of a whale on the island of Rhé, by MM. Georges Pouchet and Beauregard.—On the blood and the lymphatic gland of the Aphysia (sea-hare), by M. L. Cuénot.—On the method of union of sexual cells in the act of fecundation, by M. Léon Guignard.—On a new and dangerous parasite of the vine, by M. G. de Lagerheim. The description of the parasite is here given:—"*Uredo Vialæ:* Soris hypophylli solitariis majoribus vel dense gregariis minimis, solitariis in pagina superiore foliorum maculas parvas formantibus; uredosporis pyriformibus vel ovoideis 20μ–27μ longis, 15μ–18μ latis, membrana hyalina tenui aculeata et contentu aureo præditis, paraphysibus cylindricis curvatis incoloribus circumdatis. Hab in foliis vivis *Vitis* sp. parasitica in insula Jamaica, inter Kingston et Rockfort, Octob. 1889."—On the series of eruptions of Mézenc and Meygal (Velay); also a note on the existence of ægyrine in the phonolites of Velay, by M. P. Termier.—Composition of some rocks from the north of France, by M. Henri Boursault.—General results of a study of the carboniferous earths of the central plateau of France, by M. A. Julien.

BERLIN.

Physical Society, March 21.—Prof. du Bois-Reymond, President, in the chair.—Dr. Brodhun described a new contrast-photometer, based on the principle of one he and Dr. Lummer had previously constructed (see NATURE, vol. xxxix. p. 336), and intended to compare by contrast the intensity of any

illumination with that of the standard light. Experiment had shown that the sensitiveness of the instrument is greatest when the difference of the contrasted illuminations is 3 per cent., and amounts then to ½ per cent. He further gave an account of experiments which he and Dr. Lummer had made on the utilization of glow-lamps as standards of comparison. When fed by accumulators these lamps yield a light which only varies by 1 per cent. during a period of 200 hours provided the E.M.F. of the accumulators is kept constant. The authors are now busy with the endeavour to construct a standard glow-lamp for comparison with unknown sources of light. Dr. Lummer demonstrated Abbé's apparatus for testing transparent films with plane-parallel surfaces. After briefly describing the interference phenomena produced by thick plane-parallel glass plates, he explained how Tizeau's bands and Newton's rings are employed for testing the plates, using monochromatic sodium-light. The light passes through a reflecting prism and through a lens, and then falls on the plate, from which it is reflected and passes back by the same path to the eye, being now passed through a second lens by means of which the bands or rings may be seen. The occurrence of interference-bands is entirely dependent upon the thickness of the plate: if this is absolutely uniformly thick throughout, the interference phenomena show no change if the plate is moved from side to side in its own plane, and by so doing the parallelism of its sides may be rapidly tested.

AMSTERDAM.

Royal Academy of Sciences, February 22.—Prof. van de Sande Bakhuysen, in the chair.—Prof. Behrens added a number of reagents for microscopical analysis to those already known from former publications by himself and MM. Streng and Haushofer:—

For K and Na: sulphate of bismuth.
Ba, Sr, Ca: chloride of tin and oxalic acid.
Ba, Sr: bichromate of ammonium.
Sr, Ca, Mg: tartrate of sodium and potassium.
Al: fluoride of ammonium and sulphate of thallium.
Be: chloride of mercury and oxalic acid.
Ce, La, Di: oxalic acid, ferrocyamide of potassium.
Zn, Ca: acetate of aluminium and oxalic acid.
Zn, Cn, Co: sulphocyanide of mercury and ammonium.
Co, Ni: nitrite of potassium and acetate of lead.
Pb, Bi, Fe: bichromate of potassium and potash.
Bi, Sb, Sn: oxalic acid, chloride of rubidium.
Sb, Sn, Ti: chloride of barium and oxalic acid.

Details will soon be published, when the necessary finish has been given to the methods for separation, hitherto somewhat neglected.—M. Martin read a paper on the geology of the Kei Islands, and, in connection therewith, on the Australian-Asiatic boundary line. In accordance with the fact that in Great Kei we meet with nothing but a Tertiary formation, and that the nature of the rocks of Great Kei agrees with that of the coast of New Guinea, M. Martin inferred that this boundary line must be drawn geognostically, to the west of Great Kei and to the north-west of Timor.—Dr. Beyerinck treated of the luminous food and the plastic food of phosphorescent Bacteria. Of the six species of phosphorescent Bacteria hitherto known, four—viz. the alimental gelatine non-melting *Bacterium phosphorescens* and *B. Pflügeri* of luminous fish, and the Baltic phosphorescent Bacteria, *B. Fischeri* and *B. balticum*, require, besides peptone, a second carbonic combination, as glycerine, glucose, or asparagine, for their complete nourishment, *i.e.* to "phosphoresce" and grow. They may be called peptone-carbon-bacteria. The gelatine quick-melting phosphorescent bacteria from the West Indian Sea and the North Sea, *B. indicum* and *B. luminosum*, can phosphoresce and grow on peptone alone. They are, therefore, peptone-bacteria. Again, other bacteria can derive their nitrogen either from amids, the amid-bacteria, or from ammoniac, the ammoniac-bacteria. Also moulds, yeasts, and some Protozoa may be classed in this system. The *Bacterium Pflügeri* does emit light with peptone and glucose, but not with peptone and maltose, while the *Bacterium phosphorescens* emits light both with glucose and maltose. Now if we mix some starch in a phosphorescens-peptone-gelatine, obtained by mixing this gelatine with a very great number of *B. phosphorescens*, and place upon this some ptyaline, pancreas-diastase, or urindiastase (nefrozymase), fields of light make their appearance; if, however, we placed these same sorts of diastase on a Pflügeri-peptone-starch-gelatine, then no fields of light would appear, which proves that in this instance no glucose whatever is formed, as was lately believed to be the case. The development of luminosity is constantly accompanied by the transition of peptones into organized, living matter, under the influence of free oxygen, with or without the concurrence of another carbonic combination.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Among the Selkirk Glaciers: W. S. Green (Macmillan).—Flora Tangutica, fasc. i.: C. J. Maximowicz (Petropoli).—Enumeratio Plantarum Hucusque in Mongolia, fasc. i.: C. J. Maximowicz (Petropoli).—The Human Epic, Canto i.: J. F. Rowbotham (K. THURSDAY, APRIL 17, 1890.

THE GROWTH OF CAPITAL.

The Growth of Capital. By Robert Giffen. (London: G. Bell and Sons, 1889.)

THE popular conception of what statistics are is happily caricatured by a contemporary novelist, who describes an adept in that science stationing himself early in the morning at the entrance to a bridge, and, after scrutinizing the passengers for several hours, triumphantly reporting that exactly 2371 widows have crossed during the day. This arithmetic of the street is not the type of Mr. Giffen's calculations. His purpose is more philosophical, his method more elaborate.

The object which he seeks to measure is nothing less than the whole property, the accumulated exchangeable wealth, of the United Kindom. In this problem, to apprehend even the question requires an effort of intelligence. "Imagination shrinks from the task of framing a catalogue or inventory of a nation's property, as a valuator would make it." Reason points out that the grand total is not so much the value of the whole, which in its entirety cannot be considered saleable, as the sum of the values of all the parts, any one of which may be sold by its proprietor. The attribute of accumulation, as well as that of exchange, requires careful definition. Mr. Giffen, differing from some of his predecessors and contemporaries, does not regard the labourer himself as a species of capital. He does not, with Petty, attempt to determine the "value of the people," nor, with De Foville, to effect "the evaluation of human capital." However, some items which are of an incorporeal nature seem to enter into his account. Presumably, that part of the national capital which he reckons by capitalizing the income of public companies—multiplying it by a certain number of years' purchase—represents the value, not only of land and plant, but also of an immaterial something, which, in a broad sense, may be described as "custom" or "good will." Mr. Giffen doubts whether public debt should be admitted as an item of capital. He is certain that tenant-right should be excluded.

The uses of such a valuation are manifold. Mr. Giffen devotes a chapter to their enumeration. In the first place, it is desirable to compare our resources with our liabilities. It is satisfactory to find that the national debt compared with the national fortune is but a "bagatelle." The amount of a country's accumulations, and the rate of their increase, afford some measure of its capacity to endure the burdens of taxation, and, we may add, other kinds of pecuniary strain. It is observed by Newmarch, one of Mr. Giffen's predecessors in this department of statistics, that the investment in railways, which produced such convulsions in 1847-48, would have been in 1863 almost unfelt and insignificant in comparison with the yearly savings which were being made at the later epoch.

One use to which Mr. Giffen gives prominence may be thus described. The comparative growth of capital at different epochs serves as a sort of barometer of national prosperity. Of course those who use a barometer must remember that its indications of fair weather are but indirect and inferential. He who trusts the rising of the mercury when the north-east wind is blowing may get a wetting. So also with the metaphorical weather-glass. "The property test is useful as far as it goes, but it is not the only test," says Mr. Giffen. Elsewhere, in his address to the British Association, he has acted the part of a Fitzroy in considering together and interpreting in their connection the various tests and signs which economic meteorology affords. His object here is rather to perfect one particular instrument.

This barometrical use of capital may involve the necessity of correcting the estimates so as to take account of changes in the value of money. It may happen, it has happened, that in the last decade, as compared with the preceding period, the growth of capital estimated in money shows a falling off, while the increase of money's worth, of things, has not declined proportionately. To complete our measurement we must correct the measuring-rod. This is no easy or straightforward task. In the case of a real barometer we can mark the inches by reference to the standard yard measure, which is kept in the Tower. But a similarly perfect measure of value is, in the phrase of an eminent living economist, "unthinkable." The present generation finds itself, with respect to the variations in the value of money, in the sort of difficulty which must have occurred to the primæval man when first he may have noticed that a perfect measure of time was not afforded by the length of day and night, and before there had been constructed a more scientific chronometer. Even Mr. Giffen has to content himself with such rough and rather arbitrary corrections as the present state of monetary science affords.

As the object sought, the measure of accumulation, is somewhat hazy and difficult to envisage, so the method by which it is approached is indirect and slippery. The business man must not suppose that the estimates of a nation's capital can be totted up with the precision of a commercial account. The physicist is better prepared to appreciate the character of the computation, conversant as he is with observations which individually are liable to a certain error, while, put together, they afford certainty. But even physical observations, liable to a considerable yet calculable extent of error, hardly parallel the fallibility of these economic or, if we might coin a required word, *metastatistical* computations. In estimating that fallibility, we may usefully employ the analogy suggested by the theory of errors; but we must bear in mind the criticism to which this theory, even in its application to physics, was subjected by a witty mathematician: "After having calculated the probable error, it is necessary to calculate the probability that your calculation is erroneous."

The characteristic to which we draw attention is fully recognized by Mr. Giffen. Again and again he dwells on the rough and approximative character of his method, "the wide margin of error," and the "limit of information available." His cautions against reasoning too finely might have seemed superfluous in their iteration, but that he doubtless anticipated the irrelevant criticism which each departmental statistician might direct against details —like the specialist in sculpture who, according to Horace, represents with peculiar accuracy the hair or nails, but *nescit componere totum.*

The futility of a penny-wise precision, and even of that criticism which sticks at a few thousand pounds where millions or tens of millions are the units of the scale, will be apparent when we consider the construction of the colossal account. The starting-point of the computation is afforded by the income-tax returns. The income under each head thus evidenced is multiplied by a certain number of years' purchase to form the corresponding item of capital. Thus, in the valuation of 1885 there is, under the head of "Houses," the income £128,459,000, which, being multiplied by 15, the number of years' purchase, gives £1,926,885,000 as the corresponding entry of capital. Again, under "Farmers' Profits," the income is £65,233,000, which, being capitalized at 8 years' purchase, makes £521,864,000 capital. Now, of course, neither are the income-tax returns perfectly accurate, nor can the number of years' purchase proper to each category be assigned with precision. A further element of uncertainty is introduced when, in the case of "Trades and Professions," we reduce the income-tax return by a somewhat arbitrary factor, one-fifth, in order to take account only of that income which results from accumulated property as distinguished from personal exertion. Where the income-tax is no longer available for our guidance, the procedure becomes even more precarious. Thus "Movable Property not yielding Income," such as furniture of houses and works of art, is estimated as amounting to half the value of "Houses," that is, £960,000,000. Even the most faithful follower of Mr. Giffen may be staggered when with reference to such entries he reads—

> "The estimates of the income of non-income-tax paying classes derived from capital of movable property not yielding income, and of Government and local property, are put in almost *pro formâ* and to round off the estimates, and not with any idea that any very exact figures can be stated."

But whoever carefully considers the principles on which Mr. Giffen has assumed the different coefficients entering into his computation—principles set forth more fully in a former essay—will be satisfied that he has in no case run a risk of overrating. We may therefore accept his estimate of the national capital in 1885 as a figure round indeed, but not exaggerated. That figure is £10,000,000,000.

Greater precision may be attainable where there is required, not the absolute amount of capital in 1885, but the ratio of that amount to the corresponding estimate for 1875, in order to compare the growth of the national resources during that decade with the growth at a previous period. We shall now be assisted by the important principle which Mr. Giffen thus notices:—

> "According to well-known statistical experience, the comparison of the growth or increment may be reasonably successful, if the same method is followed on each occasion in working out the data for the comparison, although these data themselves may be unavoidably incomplete."

Let us put our *quæsitum* in the form of a fraction, thus:—

$$\frac{\text{Lands in 1885} + \text{Houses in 1885} + \text{\&c.}}{\text{Lands in 1875} + \text{Houses in 1875} + \text{\&c.}}$$

(using lands, &c., as short for value of lands, &c.). It is evident that any source of inaccuracy which exaggerates or diminishes both the numerator and denominator in the same proportion is not operative on the result. If all the data were based on income-tax returns, and the same proportion of property escaped the net of the collectors at each epoch, the result would be undisturbed.

But all the data are not based on the income-tax; nor, even if there were no increased stringency in the collection of the tax as a whole, or any other general derangement, could it be supposed that the defalcations under each head observed an exactly uniform proportion. To estimate the effects of this unequal distortion, it will be convenient to alter our statement by putting in the numerator, instead of lands in 1885, the expression—

$$\text{Lands in 1875} \times \frac{\text{Lands in 1885}}{\text{Lands in 1875}},$$

with corresponding changes for the other entries. Thus the *quæsitum* may be considered as a sort of mean—a weighted mean—of the ratios between the several items for the two years. In this expression the influence which the two elements, the absolute quantities used as *weights* and the ratios, exercise upon the error of the result is different. The influence of error in the absolute quantities would be comparatively small, if those quantities were tolerably equal and the ratios not more unequal than they are. But, unfortunately, the absolute quantities are extremely unequal. Out of the twenty-six items, "Lands" and "Houses" together make up more than a third of the sum-total. By a formula adapted to the case, it may be calculated that, if each of the twenty-six quantities be liable to an assigned error per cent. (exclusive of such mistakes as, affecting the numerator and denominator of the result in an equal proportion, disappear in the division), then the percentage of error incident to the total result is not likely to be less than $\frac{2}{5}$ths of the error affecting each of the parts. That is, abstracting the inaccuracy of the ratios, which are of the form—

$$\text{Lands in 1885} \div \text{Lands in 1875}.$$

Now any error in the ratios is more directly operative on the result than the same degree of error in the absolute quantities. But, on the other hand, it may be that the error actually affecting the ratios is particularly small, owing to the favourable operation of that general principle which we have just now cited from Mr. Giffen's pages. The estimate of inaccuracy must, however, be increased to some extent by the error of the ratios. Altogether it would seem that the whole chain or coil is not so much stronger than the particular links or strands as is usual in the calculation of probabilities. It would be a moderate estimate that the percentage error of the compound ratio is not less than a half of the error on an average affecting each of the components—lands, houses, &c.—in either year.

What degree of error, then, shall we attribute to each of these items? A precise determination of this coefficient is, as we have already observed, impossible. It would be interesting to collect the estimates of competent authorities. As a mere conjecture, for the sake of illustration, let us entertain the supposition that the error (the effective error in the sense above explained) of any one item is as likely as not to be as much as 5 per cent., and

may just possibly be 20 per cent. Then we should ascribe half this degree of inaccuracy to the figure 1·175, which, according to Mr. Giffen's computation, is the ratio of the total capital in 1885 to the total capital in 1875. It would be conceivable that the real increase, as measured by some superior being, is not 17½ per cent., but as little as 7, or as much as 27, per cent. Perhaps the defect is a little more likely than the excess, if there exist any constant cause making for depression such as the increased stringency of the tax-collectors in later years.

The growth of 17 per cent. in the decade under consideration may appear surprisingly small compared with the 40 per cent. recorded for the preceding decade. The general accuracy of the contrast is, however, confirmed by a comparison of the growths in each item for the two decades. Mr. Giffen points out that in the former decade, unlike the latter, there are no growths downwards. Also the percentages which measure increase run mostly at a higher level for the earlier period. His detailed examination of the figures leaves nothing to desire. For a summary contrast between the two sets of percentages we might submit that a proper course would be to compare the *medians* of the respective sets of figures (the arithmetic means would not be suitable owing to the very unequal importance of the figures relating to such miscellaneous items). Operating in the manner suggested, we find as the median of the first set of percentage growths 50, and of the second 25, thus confirming Mr. Giffen's conclusion that the former movement is about double the latter.

The conclusion that in the last decade our progress has been only half what it was in the preceding decade is at first sight disappointing. But we must remember that as yet we have accomplished only part of our calculation. We have still to make a correction for the change in the value of money which may have occurred between the two periods. This is a problem familiar to Mr. Giffen. In his classical computations of the changes in the volume of our foreign trade he encountered and surmounted a similar difficulty. In that case he ascertained the change in the level of prices at which exports and imports ranged in different years without going beyond the statistics of foreign trade, and by operating solely on the prices and quantities of exports and imports. It might be expected, perhaps, that he would pursue an analogous course in constructing a measure for the change of prices affecting the volume of capital. He would thus have been led to adopt the very ingenious method of measuring changes in the value of money which has been proposed by Prof. J. S. Nicholson. But, however cognate that original idea may be to the theory of the subject, it will be found in practice not easy to apply to the present computation. At any rate, Mr. Giffen has taken his coefficients for the correction in question, not, as before, from the subject itself, but *ab extra*, from Mr. Sauerbeck, Mr. Soetbeer, and the *Economist*. Averaging their results, he finds that money has appreciated to the extent of 17 per cent. during the interval under consideration. This correction being made, the growth of capital in the period 1875–85 proves to be about the same as the growth in 1865–75.

The soundness of this conclusion is confirmed by some reflections which at first sight might appear open to criticism. After using the fall of prices to prove the increase of capital, Mr. Giffen turns round and seems to reason from the increase of capital to the fall of prices.

> "If two periods are compared in which the increase of population is known to be at much the same rate throughout, and the increase of productive capacity may be assumed to be at the same rate, or not less, in one of the periods than in the other, then, if the apparent accumulation of capital in the one period proved to be less than in the other, it must be ascribed to some change in the money values."

This reasoning may appear circular to the formal logician. But, in the logic of induction, we submit that it is very proper for two arguments archwise to support each other. The consilience of different lines of proof is indeed an essential feature of the logic of fact, as formulated by J. S. Mill. We venture to interpret Mr. Giffen's double line of proof by the following parable. Has it never occurred to you, reader, on looking at your watch, and finding the hour earlier than you expected, to suspect that the instrument has played you false? You review what you have been doing; recollect, perhaps, that you began work or got up earlier than usual; and, on reflection, see no reason to distrust your watch. You test the watch by the time, and you measure the time by the watch. Similarly, Mr. Giffen is quite consistent when he measures the extent of the growth of capital by the extent of the fall in prices; and confirms the fact of a fall in prices by the independently inferred fact of a considerable growth of capital.

In connection with the fall of prices we should notice an important contribution which Mr. Giffen makes to monetary science by defining the ambiguous term "appreciation." The readers of NATURE who may be more familiar with physical than social science will smile when they understand that there has been in economical circles a stiff controversy on the following question: Whether, if there is not now in circulation a sufficient amount of money—in proportion to the quantity of commodities circulated—to keep up prices to a former level, the cause of the fall is the scarcity of gold or the abundance of goods. It is as if, when the shoe pinched, people should dispute whether the shoe is too small, or the boot too large. The mirth of the physicist seems for the most part justified. However, as Coleridge or somebody said, before we can be certain that a controversy is altogether about words, there is needed a considerable knowledge of things. The better class of controversialists in the matter before us have doubtless had a meaning, but a latent and undeveloped one, which it required our author, like another Socrates, to bring to birth. The issue appears unmeaning, as long as you consider the question in Mr. Giffen's phrase "statically," without reference to the rate at which the quantity of goods and gold are growing. But "dynamically," if goods and gold cease to move abreast, it is intelligible to attribute the separation between the two to the operation of one rather than the other. As we understand the matter, using our own illustration, let us liken the constant growth of goods to the uniform velocity of a boat carried onward by a steady stream; and the parallel increase of money to the movement of a pedestrian on the bank. If the pedestrian, after keeping abreast with the boat for some time, is at

length found to be behind it, it is reasonable to attribute the change to the man, and not the stream. But all turns upon the assumed steadiness of the stream's onward movement. Looking back on past experience, Mr. Giffen entertains the hypothesis of a constant or "normal" growth of property. But with respect to recent years, it would be possible to cite, from other high authorities, expressions of a contrary opinion. But, if the steady motion of goods is not accepted, presumably the issue between "scarcity of gold" and the opposed theory of appreciation will turn upon a comparison of the rates at which the rate of increase varies for money and commodies respectively—an investigation of *second differentials* which we could not regard as serious.

The difficulties of monetary theory do not attend some of the uses to which the estimate of national capital may be applied. It is not necessary to make a correction for the variation of money when we compare our own with a foreign country in respect of absolute quantity, and even growth, of accumulation. Our colossal capital compares not unfavourably with the capital of the United States, perhaps equal in amount, but much less per head. The £10,000,000,000 of the United Kingdom compares favourably with the £7,200,000,000 of France weighted by a heavy debt, and the surprisingly small £1,920,000,000 of Italy.

The comparison of provinces, as well as nations, is also instructive. Mr. Giffen finds that Ireland has less than a twentieth of the property belonging to the United Kingdom. The property per head in Ireland is less than a third of what it is in England, and not much more than a third of what it is for Scotland. Upon these facts Mr. Giffen remarks:—

"Reckoning by wealth, England should have 86 per cent. of the representation of the United Kingdom, or 576 members out of 670; Scotland, by the same rule, should have about 64 only; and Ireland no more than 30. . . . There should be a representation of forces in Parliament, if we had perfectly just arrangements, and not merely a counting of heads. Nothing can be more absurd to the mind of any student of politics, who knows how forces rule in the long run, than the system now established, as between the metropolitan community of England and its companions in sovereignty, by which one of the companion communities, and that the least entitled to privilege, obtains most disproportionate power."

One of the most legitimate uses to which estimates of national capital can be put, is to ascertain the progress of wealth from age to age. In an historical retrospect, Mr. Giffen reviews the work of his predecessors, rescuing from an undeserved neglect more than one writer who had the courage and sagacity to employ what Colquhoun calls "approximating facts." The succession of estimates, from the age of Petty to the present time, appears to justify the hypothesis of a constant increase of property—a five-fold multiplication per century. Contemplating the long series of records, Englishmen may reflect with pride that the increased estimates are matched by an ncreasing power of handling them, that the growth of material prosperity has not been attended by a decline in statistical genius, and that the work of Petty is continued by one who is worthy to be compared with the founder of Political Arithmetic.

MERGUI.

Contributions to the Fauna of Mergui and its Archipelago. 2 Vols. (London: Taylor and Francis, 1889.)

THE materials which have been brought together in these volumes are now made accessible to those specially interested in the fauna of this group of islands in a connected form. The collections were made in 1881-82 by Dr. John Anderson, F.R.S., till recently Director of the Indian Museum at Calcutta, who brought the specimens to England with him, and placed the different groups in the hands of specialists for their proper identification and description. The result has been the publication of a number of faunistic papers in the Journal of the Linnean Society and elsewhere, and these papers are now published in the form of two volumes, well illustrated with plates, and containing altogether nearly two dozen distinct memoirs by recognized authorities in the different departments.

In the first volume Prof. P. Martin Duncan writes on the Madrepores, and in his concluding remarks calls attention to the remarkable distinctness of the existing as compared with the Miocene corals of the same area. Prof. F. Jeffrey Bell's paper on the Holuthuria comes next in order, and is followed by Mr. F. Moore's paper on the Lepidoptera, the collection in the last order containing 208 species of butterflies, and 64 species of moths. The Sponges are described by Mr. H. J. Carter, F.R.S., and the Ophiuridæ by Prof. Martin Duncan, who contributes also a special paper on the anatomy of *Ophiothrix variabilis* and *Ophiocampsis pellicula*. The Polyzoa and Hydroida are taken in hand by the Rev. Thomas Hincks. The Coleoptera have come off badly, if Mr. Bate's description of one new species (*Brachyonychus andersoni*) represents the whole of the material collected in this order. We suspect, however, that more will be heard about the Mergui beetles at some future period.

Dr. Anderson himself contributes the list of birds, which he regards "merely as a small supplementary contribution" to Messrs. Hume and Davison's labours in the same field. The list chiefly records the distribution in the outer islands of the archipelago of a few of the species recorded by these last authors. Dr. Hoek, of Leyden, writes on a Cirriped (*Dichelaspis pellucida*), which does not appear to have been observed since Darwin published his original description in his monograph. The shells—marine, estuarine, freshwater, and terrestrial—form the subject of a paper by Prof. E. v. Martens, of Berlin. Mr. Stuart Ridley has been entrusted with the Alcyonaria, and Prof. A. C. Haddon describes two species of Actiniæ. The Annelids are treated of by Mr. Frank E. Beddard, who includes in his paper an important section on the structure of the eyes in one of the species described. The Pennatulida are treated of by Prof. Milnes Marshall and Dr. G. H. Fowler, and the Myriopoda by Mr. R. I. Pocock, this being the first list of species recorded from the archipelago. The Comatulæ are described by Dr. P. Herbert Carpenter, the Echinoidea by Prof. P. Martin Duncan and Mr. W. P. Sladen, and the Asteroidea by this last author. These organisms, when referable to known species, "show variations which are sufficient to impart a character to the collection as a whole, and to indicate

the existence of local conditions whose action upon types of a more plastic nature than that of the series of forms so far collected would probably result in new morphological developments." Mr. Sladen further throws out the suggestion that the Mergui area "may be looked upon as a moulding ground wherein Malayan types assume a modified form." A description of the physical conditions prevailing in the localities where the Asteroidea were collected is contributed by Dr. Anderson, and adds much to the value of this paper. The paper on the Mammals, Reptiles, and Batrachians is by Dr. Anderson, the three classes being represented by 23, 53, and 12 species respectively. The whole of the second volume, containing over 300 pages and 19 plates, is devoted to the Crustacea, the author entrusted with this order being Dr. J. G. de Man, of Middleburg, Netherlands. It should be added that this part of the work relates only to the stalk-eyed Crustacea.

The names of the different specialists who stand responsible for their respective contributions are sufficient guarantee that Dr. Anderson and the Calcutta Museum have been the means, aided largely by the Linnean Society, of giving to the public a substantial and trustworthy contribution to the natural history of a much-neglected group of islands. The proximity of the archipelago to the main land of course precludes the possibility of expecting much in the way of insular forms. There is one paper, however, contributed by Dr. Anderson, and forming the second part of the first volume, which will be read with interest by anthropologists, as it contains a description of a peculiar race of sea gipsies called "Selungs," who frequent the archipelago and inhabit many of its islands. These people appear to be sufficiently distinct from those of the main land to warrant their being regarded as an insular race, probably having Malayan affinities. At any rate, all that we know about them at the present time is contained in the paper referred to, which is accompanied by two photographic groups of the people, a photograph of their boats, and a lithographed plate of their weapons and utensils. There is also a vocabulary of their language, which, according to General Browne, bears not the slightest affinity to Burmese, but which Dr. Rost reports to be distinctly Malayan.

R. M.

HOW TO KNOW GRASSES BY THEIR LEAVES.

How to know Grasses by their Leaves. By A. N. M'Alpine. (Edinburgh: David Douglas, 1890.)

THIS little book will be a valuable aid to agriculturists and agricultural students. It is small, and adapted for carrying in a side pocket. It comes out seasonably, as the time is fast approaching in which its teaching may be verified in the field. It fills a gap in our knowledge of grasses, as botanists usually decide species by the inflorescence, rather than by the leaves. Colour, habit of growth, and form of leaf, are, we know, somewhat variable characters, and cannot always be relied upon; and in questions relating to the absolute identification of species, no doubt, inflorescence is of first importance. There is, however, a practical knowledge which derives immense benefit from the kind of information contained in Mr. M'Alpine's work, and after having determined approximately the component parts of a pasture in the young state, it is open to the observer to wait for further proof in the spike or panicle, which will in due time appear. A grass-field contains a larger number of species, not only of grasses but of clovers, other leguminous plants, and miscellaneous herbage, belonging to the *Compositæ*, *Umbelliferæ*, *Rosaceæ*, and other natural orders. This book treats solely of the grasses, and clearly, and with the help of 200 figures, shows how any person may identify grasses in the leafy stage. "The difficulties connected with the identification of grasses in the flowerless condition," says Mr. M'Alpine, "are not at all so great as usually supposed." This is good news from the botanist of the Highland and Agricultural Society of Scotland, Professor of Botany in the New Veterinary College, Edinburgh, and translator of Stebler's "Best Forage Plants." The great and varied knowledge of Mr. M'Alpine, is in itself a guarantee that the distinctions he has traced between the blades and stems of grasses are not of a hasty or flimsy character. Many of them are new to us, but others we have noticed ourselves, and know them to be correct. Any one furnished with a copy of this little book, and a small magnifier, will find that an additional interest will be communicated to walks in the fields, and the question as to the nature of the growing herbage of pastures may be satisfactorily answered. An eye trained to observation will be able to detect slight differences better than the eye which sees not, but we feel confidence that a careful examination of the plates and the letterpress of this little book will, if used in the field, be in itself a training in habits of observation. The book should be in the hands of every agricultural student, as it in due time will become the basis of questions at examinations. The facts that Mr. M'Alpine is himself a teacher, and that Prof. Wallace, of Edinburgh University, has written the preface, point to this conclusion.

The price for so small a book (3*s.* 6*d.*) certainly appears very heavy; but if it is called for in sufficient numbers, we shall doubtless soon hear of a cheaper edition. The demand for books of this class is small, as most farmers do not read more than is good for them, and the subject is not of great interest to the general reading public.

The classification adopted by Mr. M'Alpine is not that of genera and species. For example, rye-grasses (*Lolium*) and meadow fescue (*Festuca*) are grouped together, as having red bases to their stems; crested dog's-tail grass is peculiar for a yellow stem base; meadow fox-tail, for a dark or almost black stem base; Yorkshire fog, for having a white sheath, with red veins. These colours at the base of the stem, taken together with other characters, are used to identify the species, and the grasses which are known by the colours just enumerated form a group described as "characteristically coloured grasses." Group II. includes variegated grasses, whose leaf-blades are composed of alternate strips of white and green tissue. Group III. includes bulbous grasses, with low, flat ribs, such as Timothy grass and false oat grass. Group IV., cord-rooted grasses in hill pastures, such as mat grass and purple Molinia. Group V., acute sheathed grasses, so named on account of their sharp edges. The shoots are quite flat on the sides and the edges acute—such are cocksfoot and rough-stalked meadow grass. Group VII., bitter tasted grasses. Group VIII., bristle-

bladed grasses. Group X., hairy grasses. Group XII., ribless bladed grasses. Groups VI., IX., and XI. are separately dealt with, but those above-mentioned will sufficiently show the principle upon which the classification is made.

The figures (diagrams), showing the tapering, obtuse, flat, involute, or imbricate character of the herbage, are exceedingly plain and characteristic, and will be of great assistance to the observer in the field. The leaf-blades, stems, ligules, sheaths, &c., are well shown in cross-sections, and at length. JOHN WRIGHTSON.

OUR BOOK SHELF.

Facsimile Atlas to the Early History of Cartography, with Reproductions of the most important Maps printed in the Fifteenth and Sixteenth Centuries. By A. E. Nordenskiöld. Translated from the Swedish original by J. A. Ekelöf and Clements R. Markham. (Stockholm, 1889.)

IN this handsome volume there are 142 pages of letterpress in imperial folio, and 51 plates in double folio. It contains reproductions of about 160 of the rarest and most important maps printed before the year 1600. Among these are the 27 maps of Ptolemy, edited by Schweinheim-Buckinck in Rome, 1478 and 1490; maps from Berlinghieri's "Geographia," Firenze, c. 1478; Aeschler's and Übelin's "Ptolemy" of 1513: Reisch Margarita Philosophica, of 1503 and 1515; Lafreri's "Atlas," Romæ, c. 1570; Richard Hakluyt's "Petrus Martyr," Paris, 1587, and "Principal Navigations," London, 1599; maps of the world, by Ruysch, 1508, Bernardus Sylvanus, 1511, Hobmicza, 1512, Apianus, 1520, Laurentius Frisius, 1522, Robert Torne, 1527, Orontius Finacus, 1531, Grynæus, 1532, Mercator, 1536, Girava, 1556, de Judæis, 1593. We find also the first modern printed maps of the northern regions, of the Holy Land, of Central Europe (by Nicolas a Cusa), of France, of Spain, of England, of Russia; the first charts for the use of mariners published in print; 82 general maps, or maps referring to the New World; the first modern printed maps of Africa; the first map illustrating the distribution of religious creeds, &c.

As regards the text, chapters i.–iii. contain researches relating to the influence of Ptolemy on modern cartography, his merits and defects, and the different editions of his geography. Of the editions enumerated in bibliographical works, 27 spurious ones are neglected. In chapter iv. a review is given of ancient maps other than Ptolemaic, of the portolanos and their influence on modern geography. Chapter v. treats of the extension of Ptolemy's *Oikumene* towards the north and north-west, the pre-Columbian maps of Scandinavia and Greenland, the most remarkable of which is one discovered by Nordenskiöld himself in a library at Warsaw (reproduced on Tab. xxx.) Chapter vi. deals with the first maps of the New World, and the then recently discovered parts of Africa and Asia. Here the author draws attention to the hitherto neglected fact that maps from Vasco de Gama's second voyage were printed as early as 1513 (reproduced in the letterpress, Figs. 8–10). Chapter vii. gives an account of early terrestrial globes, and in chapter viii.—on map projection—the author corrects several errors generally adopted in the history of this part of cartography. In chapter ix. he deals with the end of the early period of cartography, and in chapter x. with the transition to, and the beginning of, the modern period. He brings out the importance of the work of Jacopo Gastaldi, Philip Apianus, Abraham Ortelius, and Gerhard Mercator, in the development of cartography. He also gives, besides a catalogue of the maps in Lafreri's "Atlas," a critical review of Ortelius's celebrated "Catalogus Auctorum tabularum geographicarum."

The work is based on Baron Nordenskiöld's private collection of ancient printed maps. This collection he began to make many years ago, and it is now rich in documents from the periods reviewed in the present "Atlas."

The maps have been excellently copied and printed, and the great care taken by the librarian, Mr. W. E. Dahlgren, has secured the correctness of the citations. All geographers who have a right to an opinion on the subject will agree that the work is indispensable to every library in which there is a department devoted to geography.

Light and Heat. By the Rev. F. W. Aveling, M.A., B.Sc. Second Edition. (London: Relfe Bros., 1890.)

THIS is a new edition of a text-book intended to prepare candidates for one of the science subjects of the London matriculation. It has been much improved since its first appearance, but it still treats the subject in a very superficial way. Although no one could seriously study the subject with this as a guide, it is certainly a useful summary of the main facts, and will probably be found serviceable by intending candidates. The coloured plate of spectra has been corrected, but surely this is superflous in a book which does not even describe an ordinary student's spectroscope. The author has fallen into the very common error of stating that the electric arc gives a continuous spectrum, and he also states that the lines in the spectra of the fixed stars are different from those which characterize sunlight; whereas in a great many cases they are practically identical.

There are numerous diagrams, but they are barely of a quality equal to those which would be produced by a student at an examination. The large collection of questions and answers will be very useful.

Warren's Table and Formula Book. By the Rev. Isaac Warren. (London: Longmans, Green, and Co., 1889.)

WE have in this small work a compact and trustworthy set of tables, facts, and formulæ which come within the scope of an ordinary education. As a reference book, it should prove most useful, the information it conveys being concise and to the point. In addition to the usual tables of weights and measures, &c., we have an account of the physical and electrical units now in use, followed by the most important formulæ used in algebra, mensuration and trigonometry, and tables of exchange, principal units of value throughout the world, and comparative average values of some important coins, the last of which will doubtless be found useful to those travelling abroad. Some of the most important business forms, such as "Form of a Joint Promissory Note," "Form of Foreign Bill of Exchange," &c., are printed in full; and the work concludes with postal and telegraph rates. On the back of the cover are printed diagrams of a square decimetre and centimetre and a square inch, together with scales of centimetres and inches.

LETTERS TO THE EDITOR.

Panmixia.

THE somewhat strained argumentation which Mr. Romanes has devoted in your issue of April 3 (p. 511) to my defence of Mr. Darwin's position in regard to "cessation of selection" and "economy of growth" does not convince me of the justice of the former's claim to have originated new principles "unfortunately" (to use his own expression) too late for Mr. Darwin to have the advantage of correcting himself by their aid. In his letter of March 13 (p. 437) Mr. Romanes lays great stress in

criticizing Weismann upon what he calls "reversal of selection," which he now tells us is the same principle as "economy of growth." Yet in the earlier letter he entirely omits to credit Mr. Darwin with the recognition of that principle, and after carefully asserting that Mr. Darwin had overlooked the principle of "panmixia," he gives in an historical form what *he* (Mr. Romanes) had argued some years ago, and what *his* views were—including herein the principle of economy of growth, or more generally, reversed selection. Now that the oversight has been pointed out to him Mr. Romanes allows that "it is a matter of familiar knowledge that Mr. Darwin at all times, and through all his works, laid considerable stress upon the economy of growth (or more generally, reversed selection)."

Mr. Romanes makes an unreal separation between "cessation of selection" and "reversal of selection"; at the same time, for the mere purpose of *badinage*, he affects to suppose that I do not perceive any difference between them—a supposition which cannot be sincere in view of the statements in my letter of March 27. Cessation of selection is not a "principle" at all. It is a condition which alone cannot produce any important result. At the same time, what Mr. Romanes misleadingly calls "reversal of selection," viz. "economy of growth," cannot become operative in causing the dwindling of an organ until the condition of "cessation of selection" exists. The fact is—as Mr. Romanes insisted before it was pointed out in these pages that it was no new principle of his own discovery, and when he wished to lay claim to an improvement upon Weismann's exposition of "panmixia"—cessation of selection must be supplemented by economy of growth in order to produce the results attributed to "panmixia." And inasmuch as economy of growth as a cause of degeneration involves the condition of cessation of selection, Mr. Darwin, in recognizing the one recognized the other.

By the use of the term "the principle of the cessation of selection" Mr. Romanes has created an unnecessary obscurity. To say that a part has become "useless," or "has ceased to be useful to its possessor" as Mr. Darwin does, is clearly the same thing as to say that it "has ceased to be selected"—selection and use being inseparable. Mr. Darwin states that such parts "may well be variable, for their variations can no longer be checked by natural selection." That is panmixia. It is true that Mr. Darwin did not recognize that such unrestricted variation must lead to a diminution in size of the varying part without the operation of the principle of "economy of growth." This was no strange oversight: he would have been in error had he done so. On the other hand, he did recognize that, given the operation of that principle, the result would amount to the dwindling and degeneration of parts which are referred to as rudimentary.

"Panmixia" as a term clearly refers to the unrestricted interbreeding of all varieties which may arise, when selection in regard to a given part or organ is no longer operative. The term, like its correlative "cessation of selection," does not indicate a principle but a natural condition: it does not involve the inference that a dwindling in the *size* of the organ must result from the inter-breeding; but simply points to a precedent condition.

I am by no means prepared to admit that panmixia alone (*i.e.* without economy of growth or other such factors) can be relied upon, as it is by Mr. Romanes, to explain the reduction in size of the disused organs of domesticated animals. I observe that in his letter on this subject to NATURE of April 9, 1874, Mr. Romanes does not attempt to attribute a dwindling action to "panmixia" alone, but assumes a limitation by economy of growth to any increase beyond the initial size of the organ which has become useless. Given this limitation and the condition of panmixia, the dwindling follows; but it is absurd to attribute the result, or any proportion of it, to the panmixia or cessation of selection alone. On the other hand, when we consider shape and structure, and not merely size, it is clear that panmixia without economy of growth would lead to a complete loss of that complex adjustment of parts which many organs exhibit, and consequently to degeneration without loss of bulk. That the principle of economy of growth is ever totally inoperative has not been demonstrated.

E. RAY LANKESTER.

April 9.

Heredity, and the Effects of Use and Disuse.

ALL biologists will, I am sure, agree as to the desirability of a thorough testing of the hypotheses relative to the inheritance of the effects of use and disuse. As Mr. Spencer says, in the preface to "The Factors of Organic Evolution":—"considering the width and depth of the effects which acceptance of one or other of these hypotheses must have on our views of Life, Mind, Morals, and Politics, the question—Which of them is true? demands, beyond all other questions whatever, the attention of scientific men."

As experiments suggested by those who believe in the inheritance of the effects of use and disuse would hardly carry the weight to those who do not believe in this inheritance which experiments proposed by themselves would, I write to suggest the desirability of undertaking an investigation which, Prof. Weismann thinks, would prove one or other hypothesis. He states it in the following words on p. 91 of the English edition of his "Essays":—

"If it is desired to prove that use and disuse produce hereditary effects without the assistance of natural selection, it will be necessary to domesticate wild animals (for example the wild duck) and preserve all their descendants, thus excluding the operation of natural selection. If then all individuals of the second, third, fourth, and later generations of these tame ducks possess identical variations, which increase from generation to generation, and if the nature of these changes proves that they must have been due to the effects of use and disuse, then perhaps the transmission of such effects may be admitted; but it must always be remembered that domestication itself influences the organism,—not only directly, but also indirectly, by the increase of variability as a result of the suspension of natural selection. Such experiments have not yet been carried out in sufficient detail."

If Profs. Weismann, Romanes, and Lankester, would agree to some such experiment as the above as definitely proving the point in question (I say "definitely," for the sentence which reads "if the nature of these changes proves that they must have been due to the effects of use and disuse," seems rather to beg the whole question, even if the experiment were carefully carried out), there are two ways in which it might be effected. One is, that the British Association, which by devoting time to the discussion of the hypothesis has shown an appreciation of its worth, should at its next meeting appoint a committee, with a small grant for necessary expenses, to carry out the investigation. The other is, that it should be undertaken independently by the foremost of those on both sides who are interested in this question, and who would no doubt subscribe among themselves enough for the purpose in view—at least, speaking for myself, I should not object to contribute to the expenses of a properly planned investigation.

Regarding the place where the "wild ducks," or possibly some animal with a more frequent recurrence of broods, should be located for observation, I would suggest that the Zoological Society should be asked to afford space in their Gardens at Regent's Park.

F. HOWARD COLLINS.

Churchfield, Edgbaston.

Galls.

THE difficulty raised by Mr. Wetterhan (NATURE, February 27, p. 394) appears at first sight a serious one, but I think it vanishes on examination. Supposing the attacks of the insects to be constant, trees in their evolution would have to adapt themselves to these circumstances, just as they have adapted themselves to the environment of soil, air, light, wind, and so forth. But the fallacy (as it seems to me) of Mr. Wetterhan's argument lies in the supposition that the life of an oak-tree as such, and the life of an insect, may rightly be compared. A tree is really a sort of socialistic community of plants, which continually die and are supplanted by fresh. Bud-variation is a well-known thing, and in oaks A. de Candolle found many variations on the same tree. Now is it unreasonable to suppose that internal-feeding insects might take advantage of such variation—or rather, be obliged to take advantage of it, if it were in a direction to benefit the tree? I will give two purely hypothetical instances, to illustrate the points involved. Imagine two oak-trees, each with three branches, and each attacked by three internal-feeding insects. The insects infesting one tree are borers; those on the other tree are gall-makers. The borers bore into the branches, which they kill while undergoing their transformations: the tree possibly does not die that year, but next year the progeny of the three, being more numerous while the tree is weaker, effect its destruction, and finally the insects perish for want of food. On the other tree, the gall-makers do no appreciable damage, and the tree is

able to support them and their progeny without great difficulty. Now a little consideration will show that the longer the life and the slower the reproduction of the trees, the greater will be the contrast. If the plant infested by the borers had been an annual herb, it might have contrived to perfect its seeds, and the death of the old stem would be but a natural and inevitable process, and fresh plants might have been produced in sufficient numbers to continue the species in spite of all insect-attacks. But in the case of trees—oak-trees especially, the rate of growth and reproduction is such that, unless the insect-borers can live in galls, they will destroy the plants entirely, and themselves in consequence. Indeed, I have no doubt, that if all the gall-makers now existing could suddenly be transformed into stem-borers, the genera *Quercus*, *Rosa*, and *Salix*, now so dominant, would shortly disappear from off the face of the earth. The other hypothesis—here assuming that the production of galls is due more to the tree than the insect—is this. Suppose an oak-tree with four branches, all attacked by internal-feeding insects. Two of the branches produce swellings in which the insects live, while the other two produce none, and the insects have to devour the vital parts. Now the two branches which produced no swellings would quickly be killed by the insects, but those which produced galls would live, and the more perfect the galls, the greater the insect-population they would be able to support. Hence the tree would finally, by the survival of its gall-producing branches, become purely gall-producing, and we may assume that its progeny would inherit the peculiarity.

I am aware that the above arguments will sound a little like those of the Irishman, who said he ought not to be hanged, because, "in the first place, he did not kill the man; in the second place, he killed him by accident; and thirdly, he killed him in self-defence,"—but I do not represent either of the above hypotheses as the precise truth of the matter, and I think they sufficiently illustrate the principles involved.

T. D. A. COCKERELL.

West Cliff, Custer Co., Colorado, March 16.

On the Use of the Edison Phonograph in the Preservation of the Languages of the American Indians.

THE present state of perfection of the Edison phonograph led me to attempt some experiments with it on our New England Indians, as a means of preserving languages which are rapidly becoming extinct. I accordingly made a visit to Calais, Maine, and was able, through the kindness of Mrs. W. Wallace Brown, to take upon the phonograph a collection of records illustrating the language, folk-lore, songs, and counting-out rhymes of the Passamaquoddy Indians. My experiments met with complete success, and I was able not only to take the records, but also to take them so well that the Indians themselves recognized the voices of other members of the tribe who had spoken the day before.

One of the most interesting records which was made was the song of the snake dance, sung by Noel Josephs, who is recognized by the Passamaquoddies as the best acquainted of all with this song "of old time." He is always the leader in the dance, and sang it in the same way as at its last celebration.

I also took upon the same wax cylinder on which the impressions are made his account of the dance, including the invitation which precedes the ceremony.

In addition to the song of the snake dance I obtained on the phonograph an interesting "trade song," and a "Mohawk war song" which is very old. Several other songs were recorded. Many very interesting old folk-tales were also taken. In some of these there occur ancient songs with archaic words, imitation of the voices of animals, old and young. An ordinary conversation between two Indians, and a counting-out rhyme, are among the records made.

I found the schedules of the United States Bureau of Ethnology of great value in my work, and adopted the method of giving Passamaquoddy and English words consecutively on the cylinders.

The records were all numbered, and the announcement of the subject made on each in English. Some of the stories filled several cylinders, but there was little difficulty in making the changes necessary to pass from one to the other, and the Indians, after some practice, were able to "make good records" in the instrument. Thirty-six cylinders were taken in all. One apiece is sufficient for most of the songs and for many of the short . The longest story taken was a folk-tale, which occupies nine cylinders, about "Podump" and "Pook-jin-Squiss," the "Black Cat and the Toad Woman," which has never been published. In a detailed report of my work with the phonograph in preserving the Passamaquoddy language, I hope to give a translation of this interesting story.

Boston, U.S.A., March 20. J. WALTER FEWKES.

Solar Halos and Parhelia.

A MAGNIFICENT display of solar halos and parhelia was witnessed here this afternoon, exceeding in beauty and brilliancy that observed on January 29, 1890, and described in NATURE, February 6, p. 330.

The phenomenon was similar to the one of January 29, except that the mock suns were distinctly outside the first circle or halo, at a distance of 5° or 6°, and were when first seen at 3 p.m. *above* the level of the true sun; a handkerchief stretched at arm's length from one to the other gave the blurred image of the sun several degrees lower.

At 3.49 the patch of white light appeared about 90° from the right mock sun and connected to it with a *curved* band of white light, concave side upwards. The right mock sun must then have been *below* the level of the sun, as the band appeared to pass upwards through it to the sun. This band only remained a few minutes; the right sun and zenith arc at the time were most intensely brilliant, with the colours exceptionally clear and vivid. The zenith arc, and the patch of white light, were the last to disappear at 4.22.

The cirro-stratus cloud during and after the display was rapidly advancing from the north.

Driffield, April 9. J. LOVELL.

Cambridge Anthropometry.

I HAVE read with much interest, in NATURE of March 13 (p. 450), Mr. Venn's very interesting article on anthropometry at Cambridge.

There is in his tables one rather peculiar feature, of which I find no notice taken in the text. It will be seen on reference to the tables that, while the other physical characteristics increase from A to B, and from B to C (weight and height being irregular, however), the *breath* is highest in A, less in B, and least in C; thus falling with the intellectual fall.

It is true that the difference in this as in most of the other characteristics is so slight as to be—as Mr. Venn says—practically negligible; but still the fact that this should steadily *fall* instead of rising with the other physical characteristics strikes me as peculiar. I should be glad therefore to hear if Mr. Venn has any comment to make on this phenomenon, or any explanation thereof to suggest. F. H. P. C.

April 4.

A Remarkable Meteor.

ON Thursday, April 10, at 10.40 p.m., I observed a meteor of extraordinary brilliancy shoot from a point just east of β Leonis. It travelled over about 10° in a north-westerly direction, and was visible for fully two seconds. Its apparent diameter, as nearly as I can judge, was about a quarter of that of the full moon; its colour, a very vivid pale green. J. DUNN.

Much Marcle, Herefordshire, April 11.

Earthworms from Pennsylvania.

NEARLY twenty years ago, a very aberrant earthworm was described by a French naturalist, who obtained it from Pennsylvania. I should be greatly indebted to any naturalists or travellers who may find themselves in that part of the United States, if they would collect some of these worms and send them to me. The most convenient mode of transmission would be to pack the living worms in *moist* earth with moss or grass, in a tin box perforated at one end: this should be inclosed in a wooden box. Both small and large worms should be collected: some might be preserved in strong spirit, but living specimens would be the most useful. W. BLAXLAND BENHAM.

University College, London, April 10.

Crystals of Lime.

SINCE the appearance of my letter on this subject (p. 515) I have found that similar crystals have been recently observed by Mr. J. Joly, and were described by him in the Proceedings of the Royal Dublin Society, vol. vi. p. 255. H. A. MIERS.

SAMPLES OF CURRENT ELECTRICAL LITERATURE.[1]

THESE four books are samples of the different classes of text-books of the present day. The first, as its title implies, is intended for workmen actually engaged in the electrical industries, and is therefore of the non-mathematical technical order. The second, on the other hand, is intended for the practical man who is not afraid of a differential equation, and is a very suitable book for a student of one of the higher technical colleges. The third is a mathematical treatise of the University type; while the fourth is intended for the general public unacquainted with mathematical or scientific principles, but anxious to learn something about this electricity and its distribution, which are now constantly being referred to even in the daily newspapers.

Of the four books, the second, on "Absolute Measurements in Electricity and Magnetism," is the most valuable, because the information it contains is correct, and much of it is not to be found in other books. On opening the first book, "Short Lectures to Electrical Artisans," we anticipated seeing how Dr. Fleming had struck out an entirely new line; but we must confess our disappointment at finding that the author has such a veneration for the authority of antiquity that he felt compelled to commence this book with a description of the loadstone. These lectures, we are told in the preface to the first edition, are on "subjects connected with the principles underlying modern electrical engineering," and were delivered "to the pupils and workmen associated with" Mr. Crompton's firm at Chelmsford. We presume, then, that the lectures were intended to enable workmen to make better dynamo machines, electromotors, &c., but as we never yet met with a piece of loadstone in any electrical factory in England or the Continent, we fail to see how the purpose of the lectures was served by their starting with an account of the "native oxide of iron" called the loadstone. Neither the loadstone nor the classical lump of amber, so dear to the hearts of the writers of electrical text-books, are workshop tools. The latter a workman may perhaps come into contact with as a mouthpiece to his pipe, but a piece of loadstone he will probably never even see out of the lecturer's hand. Apart from this academic start, Lecture I. is decidedly good; the author, for example, not merely mentions that an alloy of steel with 12 per cent. of manganese is nearly non-magnetic, but he gives the name and address of the firm from whom manganese steel can be obtained, and he follows the same wise course when explaining how ferro-prussiate photographic paper may be used for obtaining permanent records of magnetic lines of force.

But why give Rowland's curve connecting permeability and magnetic induction, since later experiments have shown that this curve is quite wrong for large magnetic inductions? The same mistake is made in Lecture III., where it is assumed that for a certain magnetizing force iron becomes saturated, so that no greater induction can be produced, no matter how much the magnetic force is increased.

Lectures II. and III. have many blemishes. The expression 50 ampères of current, on p. 24, is misleading; you cannot have 50 amperes of anything else but current. An ampere is the English name for a unit of current; why, then, put a grave accent over the name? One might as well in speaking of so many metres give this last word its French pronunciation? In justice, however, to Dr. Fleming, we should mention that the use of the grave accent over the word *ampère*, when used in English, is not peculiar to him. We wish, however, that he had been bold enough to Anglicize this word. In describing the construction of a simple mirror galvanometer, the *technical* reader ought to have been warned that, unless, in sticking the three magnets on the back of the mirror with shellac varnish, the shellac be put just at the middle only of each magnet, the mirror will be distorted and rendered useless. To say, when speaking of the induction of a current in a secondary coil by the starting or stopping of a current in the primary, that the interposition of "a plate of iron prevents it altogether," shows that the author has never tried the experiment.

On p. 30 is given a picture of the apparatus the author employs for ascertaining the laws of the production of a current in a coil by the insertion or withdrawal of a magnet. The magnet that is being moved has, judging from the figure, at least 1000 times the mass of the needle of the galvanometer, which is attached by two *very short* wires to the coil in which the current is induced. If an electrical artisan were to perform this experiment with the apparatus placed as in Fig. 17 of Dr. Fleming's book, he would probably ascertain the laws of magneto-electric induction with the same amount of accuracy as we once saw obtained at a lecture where the decisive, and applause-producing, swings of the galvanometer needle, on suddenly bringing up the magnet to the coil and removing it again, were certainly produced by the *direct* action of the magnet on the galvanometer needle, since it was observed at the close of the lecture that one of the wires going from the coil to the galvanometer had never been connected with the galvanometer terminal. And the same sort of criticism applies to Fig. 28, p. 57, representing the arrangement of apparatus for measuring the magnetization of the iron core of an electro-magnet by a current passing round its coil. The reader is told that the magnetometer, which is, of course, to be directly affected by the magnetism of the iron bar, is, for some reason unexplained in the book, to be put at a considerable distance from the bar, but he is not warned that the meter used for measuring the current passing round the electro-magnet (and which, of course, ought not to be directly affected by the magnetism of the bar) must on no account be placed, as in this figure, close to the powerful magnet.

On p. 32 the author says that a core of soft iron "acts like a lens, and concentrates or focusses more lines of force from the magnet on the primary coil through the aperture of the secondary." But this simile with a lens is but a repetition of an old error; a lens simply bends rays of light, and, so far from adding to the total amount of light, actually slightly diminishes this amount by absorption. A lens for light is like a funnel for a fluid, it directs the stream along a narrow channel, so that while the flow is on the whole diminished by friction the flow along a certain cross-section is much increased. But the insertion of an iron core into a coil traversed by a current vastly increases the *total* number of lines of force. The solenoid without the iron core is like a cistern with water in it which is being emptied with a pipe full of dirt, through which the water can only trickle; and the insertion of the iron core into the solenoid is like the cleaning out of the pipe, so that the stream of water now becomes vigorous and rapid. Even Dr. Fleming knocks his own simile on the head, for he states 27 pages further on, "The joint effect of the" (iron) "bar and coils is the sum of the effects of each separately." Fancy anyone saying that the joint effect of a lens and a candle was the sum of the effects of each separately.

We consider it archaic for Dr. Fleming to define the volt for practical men as the E.M.F. generated in one centimetre of wire moving with a velocity of one centimetre per second in a magnetic field of unit force. As well

might a kilogramme be defined for a French butcher as the weight of a cubic decimetre of distilled water at 4° C., and the butcher's business be absolutely stopped because he did not possess any distilled water and because the temperature of his shop was 20° and not 4° C. In fact, Lectures II. and III., although containing a large amount of valuable information, are professorial rather than practical.

On p. 74 a Ruhmkorff induction coil is correctly described, but in Fig. 36 on the same page the primary coil, with the vibrating interrupter and four cells in its circuit, is shown as consisting of many convolutions of fine wire, and the secondary of a few turns of thick wire. On p. 83 one centimetre is given as equal to 0·0328087 of a foot—that is, correct to *six significant figures*—while even in the second edition, "the call" for which "has afforded the opportunity to erase several typographical errors and to remove some other blemishes which had escaped notice and correction in the first edition," the previous statement is *immediately* followed by the announcement that one inch equals 2·500 centimetres, an equation which is only correct to *two significant figures*, the number expressed correctly to six significant figures being 2·53995. But why not use 2·5400, the value commonly adopted, and which is correct to four places of decimals? As a further example of the want of precision which runs through this book, it may be mentioned that on p. 9 a falling body acquires per second a velocity of 981 centimetres per second. Throughout the whole of p. 85, where the number is frequently mentioned, the body, as if a little tired, cannot get up a velocity of more than 980 centimetres a second. Proceeding, however, to the next page, the body, like the reader, turns over a new leaf, and hurries up its speed, for it acquires per second a velocity of 981 centimetres per second all through this page. Further on, however, in the book, the poor falling body gets tired again, for on p. 97 it cannot do more than the 980. On p. 87 we find the statement, "Hence one foot-pound = 1·356 *joules*, or one joule = ·7373 foot-pound," whereas a simple division shows that if the first part of the statement be correct, the second is not.

To say that "the work is numerically measured by the product of the displacement and the mean stress estimated in the direction of the displacement" is learned and academical, but might not the poor electrical artisan mix this up with the displacement of the factory hands that usually occurs when there is no stress of work?

On p. 99 it is stated that the "E.M.F. of Clark's cell = 1·435 true volt," but, as no indication has been given in this book that there is more than one volt, we are left in ignorance of the reason why the volts used to measure the E.M.F. of a Clark's cell have to be *so especially true*, and why 10^8 C.G.S. units, which is the volt that has been previously used, is not good enough for this sort of measurement. On looking in the index for the definition of the "Ohm British Asssociation," we find ourselves referred to p. 136, and the reader is left to wonder what is a "B.A.U." of resistance used some forty pages previous to this. Similarly the "Legal Ohm" is spoken of and its value given in terms of a "B.A.U." thirty-seven pages before the reader is told what a "Legal Ohm" is. For this the arrangement of the book and not the index is, of course, to blame. And while on this subject we should like to point out that the indexes of scientific books appear to furnish a conclusive proof of the inherent modesty of scientific writers. Take up some large and important treatise, and turn to the index. There you are told that the book contains almost nothing. On the title-page the publisher may have indiscreetly added after the author's name line after line of small print enumerating the various scientific and unscientific societies to which the author belongs, but in the index all pretension to such a wide acquaintance with science is disclaimed. You may have a distinct recollection of reading in this very book many pages on some special subject, but rack your brains as you will to discover under what heading in the index this subject may have been entered, not a reference to it can you find. Accumulators, storage cells, transformers, the volt, voltmeters, &c., seemed likely subjects to be treated on in "Short Lectures to Electrical Artisans," but the index says no; and it is only by carefully reading through the book that you discover that it contains much valuable information on these very points. We would suggest to the writers of scientific treatises, and also to those who communicate scientific papers to learned societies, that the practical man of to-day cannot possibly afford the time to read through ninety-nine things that he does not want to know about, before he can light on the one thing regarding which he is searching for information.

In speaking of Messrs. Crompton and Kapp's meter, on p. 115, Dr. Fleming says:—

"The only difficulty which arises in connection with such an instrument as this, is the tendency of a long thin iron wire of this kind to retain strongly residual magnetism and fail to de-magnetize itself, but this effect would only prevent the return of the indicating needle to zero when the current was stopped, but would not prevent the instrument from giving a definite and fixed deflection corresponding to a definite and fixed current passing through the coils." It was no doubt a somewhat delicate task for Dr. Fleming when lecturing to Mr. Crompton's staff to fully criticize Mr. Crompton's meters, but since actual published experiments on some of these meters show that, for the low readings, the apparent value of a given current differs by as much as 10 per cent., depending on whether the current is ascending or descending, we fail to see how the scientific knowledge of any artisans can be improved by their being told that no such error exists.

Fig. 50, p. 122, showing the level of the columns of water in stand-pipes attached to a horizontal tube through which water is flowing, was never drawn from an actual apparatus. The author has forgotten that the water has not merely to flow through the horizontal tube A*a*, but through the much longer vertical tube CA, and therefore, there is a much greater difference of level between the height of the water in the cistern and in the first stand-pipe, *aa'*, than there is between the level in this stand-pipe and in the next, *bb'*. If Fig. 50 were correct, it would follow that when a battery of even *large internal resistance* was sending a considerable current the difference of potentials at its terminals was equal to the E.M.F. of the battery. Not merely, then, is this opportunity lost of explaining to the readers that the difference of potentials at the terminals of a battery may be very much less than the E.M.F., but the information conveyed by the diagram is actually contrary to fact.

The statement that "Storage cells for lighting purposes cease to give a useful discharge when the electromotive force falls below two volts" is hardly consistent with the fact that, when storage cells are discharged at the current that is considered quite safe by the Electrical Storage Power Company, the E.M.F. for nine-tenths of the period of the discharge is slightly below two volts.

We have said enough to show that, although the book called "Short Lectures to Electrical Artisans" is written by one who, from his University and factory experience, has a large amount of valuable information at his command, the second edition reads far too much like an uncorrected proof of the first edition; and instead of the statements it contains possessing weight because they are made in the book, there is an uneasy feeling when reading its pages that any statement may be wrong, and requires to be checked. We trust, however, that the sale of this, the second edition, may be large and rapid, so that the author may have an opportunity of shortly bringing out as a third edition a book more worthy of his acknowledged power.

"Absolute Measurements in Electricity and Magnetism," by Prof. A. Gray, is a most interesting book to read. It opens with a detailed description of Gauss's methods for determining the horizontal intensity of the earth's magnetism, and with an account of the results of the measurement of the variation, produced by a unit field, on the magnetic moments of steel magnets of different sizes tempered to different degrees of hardness. If it be desired to determine the magnetic moment of a bar-magnet as well as the horizontal intensity of the earth's magnetism, which is of course necessary when variations of the magnetic moment of a bar are in question, Gauss's methods are admirable. But if the value of H is all that is needed, then the simpler method of employing an earth inductor with a ballistic galvanometer, which is described on pp. 317-21, might well be employed. It would, therefore, have been well to give a reference to this method in the first two chapters, which are mainly devoted to the determination of H.

Next follows a concise statement of the various ways of defining the absolute current, and a fairly complete chapter on standard galvanometers. In Chapters IV. and V., and in Chapter XI., to which reference is made, there is given the ablest description of the dimensions of the electric and magnetic units that we have ever read. It is both correct and comprehensible, which is saying a very great deal for an exposition of a subject which, as usually explained, generally leaves even a thoughtful student semi-dazed as to whether the dimensions are the dimensions of the unit, or the dimensions of a quantity measured in the unit. Indeed, the early reports of the Electrical Standards Committee of the British Association were actually wrong on the very subject of dimensions, so that "*v*" was regularly defined as the ratio of the electrostatic to the electromagnetic unit of quantity instead of as the reciprocal of that expression.

The volt, ohm, ampere, coulomb, watt, and joule are also explained and defined in Chapter V., and Prof. Gray gives Sir W. Thomson's expression "activity" for the rate of doing work. He does not mention, however, that the equally short word "power" is regularly employed with this signification.

Chapter VI. is devoted to the laws of the currents sent by galvanic cells through single and parallel circuits, and through any branch of a network like that of the Wheatstone's bridge. A neat proof is given of the arrangement of a given number of cells that sends the greatest current through a fixed resistance, and the reader is very properly warned against confusing the arrangement which develops maximum power with the most economical arrangement.

In Chapter VII. we have a complete description of Sir William Thomson's meters, but, as the book is a scientific treatise (in fact, a very good scientific treatise) and not an instrument-maker's catalogue, we think that the author would have done himself more justice had he described, in addition, some of the other many forms of electric meters in common use at the present day for carrying out the same measurements. Further, in view of the large experience that the author of this book has probably had with Sir W. Thomson's meters, it would have been well had there been a description not merely of the advantages of these instruments, but also of their disadvantages, a subject no one would be more willing to discuss than the inventor himself. On pp. 133-35 is given a very simple proof of the ordinary formula for the quadrant electrometer, but the reader is not here warned that the formula may give an answer many per cent. wrong in practice. On p. 302 it is stated that this formula may be slightly wrong if the aluminium needle of the electrometer be not accurately adjusted relatively to the quadrants, but this, we fear, is rather misleading, since it is further stated that "if the needle hangs at its proper level, and is otherwise properly adjusted, and the quadrants are close, the equation may be taken as accurate enough for practical purposes," a conclusion regarding which we understand there is grave doubt. In this chapter the very important subject of calibrating instruments by the use of the silver or the copper voltameters is fully entered into. The large amount of valuable work done on this subject by the author's brother, Prof. T. Gray, of which a description is given, endows this chapter with an authoritative character.

Chapter VIII. commences with the construction and use of the various forms of Wheatstone's bridges, the description of the modes of using them, and hints as to the care of a resistance box. The methods for calibrating relatively and absolutely the wire of a bridge devised by Matthiessen and Hockin, Foster, T. Gray, and D. M. Lewis are discussed at length, and specimens given of the actual results obtained at University College, North Wales, by the use of these methods. The ingenious bridges, which have been arranged by Sir W. Thomson, Matthiessen and Hockin, Tait and T. Gray, for measuring very low resistances, are fully entered into, and the construction of standard coils, the measurement of high resistances, and of the resistance of a battery finish a chapter of especial interest. The method of measuring the resistance of a battery, proposed several years ago by Sir Henry Mance, is condemned by Prof. Gray as being "so troublesome as to be practically useless," on account of "the variation of the effective electromotive force of the cell produced by alteration of the current through the cell which takes place when the key is depressed." We think that it should have been stated that this is not a defect especially of Mance's method, but of *all* methods for measuring the resistance of a battery based on the alteration of a steady current by the alteration of the resistance in the battery circuit. Would it not also here have been well to describe and discuss the condenser method of measuring a battery resistance, as it is the one to which the fewest objections can be raised?

Good as are all the chapters in this book, the next one, Chapter IX., on "The Measurement of Energy in Electric Circuits," is so good that it takes the palm. It commences with the practical methods of measuring the power and efficiency of motors and secondary batteries; the construction and employment of activity meters (watt-meters); and then discusses very fully the laws of alternate currents, the mathematical theory of alternate current generators singly, or coupled in parallel or in series; the theory of the action of an alternate current generator supplying current to an alternate current motor; the true method of measuring the power given to any circuit by an alternate current; and the error produced when an ordinary watt-meter is employed. The work of Joubert, Hopkinson, Potier, Ayrton and Perry, and Mordey on this subject is summed up in a masterly fashion. Chapter IX. is, in fact, the most complete exposition of many problems connected with the all-important subject—the electrical transmission of energy by *alternate* currents—that is to be found in any existing text-book, and especially in a small octavo text-book, that can be easily carried in one's coat pocket.

In Chapter X. the measurement of intense magnetic fields is dealt with, and a description is given of ingenious methods proposed by Sir W. Thomson for measuring the force on a conductor conveying a known current placed in the magnetic field, and so determining the strength of the field. The ordinary method of ascertaining the strength of a magnetic field by suddenly withdrawing a coil, of known area and number of convolutions, attached to a ballistic galvanometer, is described. But in order to ascertain the constant of the ballistic galvanometer, the author only gives the old method of observing the swing of the needle when a large coil is turned in the earth's field, a method which necessarily requires for its employment a previous knowledge of the strength of the earth's field at the place. A far simpler method of ascertaining the constant of a ballistic galvanometer is to charge a

condenser of known capacity with one or more Clark's cells, of which the E.M.F. at any ordinary temperature is now well known, and discharge the condenser through the ballistic galvanometer; or, if a sufficiently delicate ampere-meter be available, the ballistic galvanometer may be very accurately calibrated for steady currents, and then its constant for a sudden discharge is at once known by simply measuring, in addition, the periodic time of vibration of the needle and its logarithmic decrement.

The book concludes with an appendix giving the decisions arrived at in 1886 by the Electrical Standards Committee of the British Association, and the further resolutions which were passed at the meeting of the Electrical Congress in Paris last year, and subsequently agreed to by the British Association Committee. Then follow twelve sets of useful tables.

Although we have made a few suggestions that the author may perhaps like to adopt in publishing the third edition of his "Absolute Measurements in Electricity and Magnetism," we desire to emphasize our warm appreciation of this the second edition. On every page may be seen evidences of the firm grip of the subject so characteristic of the author's teacher—the teacher, in fact, of us all—Sir William Thomson; and did we know of higher praise than this we would give it.

"The Theory and Practice of Absolute Measurements in Electricity and Magnetism, Vol. I.," also by Prof. A. Gray, is a mathematical expansion of the *electrical* portion of his book on "Absolute Measurements, &c.," the mathematical treatment of the *magnetic* portion being reserved for Vol. II. of the larger work. As many of the remarks that we have already made regarding the smaller work apply equally well to the larger, it is unnecessary to criticize the larger book at any considerable length. The two books may be read quite independently of one another, since much of the descriptive matter is the same in both. If there be a fault in the larger work, we think that it arises from the author forgetting that a book intended initially for the University student can also be made of great value to the more practical electrician if first the subject-matter be arranged in propositions, or with distinct headings to the paragraphs, so that it is easy to find the proof of any particular fact; and, secondly, if complete proofs be given of important practical problems, instead of simply deducing them as special cases of more general problems. For example, a practical electrician may desire to see how the logarithmic formula for the capacity of a cable is arrived at. Now, there is no difficulty in giving a fairly short complete proof of this; but, on turning to Prof. Gray's "Theory and Practice, &c.," the electrician finds that he must first master the theory of charged ellipsoids; he sees several double integrals and several lines of long mathematical formula in small print, and he probably decides that he had better pass by that subject for the present. We hold that, since the pure science of electricity owes so much to its practical development, it is but fair that the pure mathematician should endeavour to repay this debt by stating his results and methods of proof in such a form that they can be most easily grasped by anyone who desires to use them, and not merely to get up the subject for examination purposes. The general mathematical investigations are also, of course, of great value, and we are therefore glad to see in this book a fairly complete mathematical treatment of Green's theorem, inverse problems, electric images, problems of steady flow in non-linear conductor, and variable linear flow, with its application to the speed of signalling in submarine conductors.

Very interesting information is given regarding the strength and torsional rigidity of the fine silk fibres used in suspending galvanometer needles, followed by the mathematical theory of oscillations, the description of the practical methods of measuring periodic times of oscillation and moments of inertia, and concluding with a comparison of unifilar and bifilar suspensions. The succeeding chapters on electrometers, the general measurement of resistance, the calibration of the wire of a metre bridge, the measurement of very low resistances, the measurement of very high resistances, the determination of specific resistance, contain what is given on these subjects in the smaller book amplified.

The last chapter, No. VIII., in this larger treatise, on capacity, is very complete. It gives a description of the most important investigations that have been made on the specific inductive capacity of solids, liquids, and gases, together with the mathematical theory of each experiment.

Although we cannot but feel that the smaller of the two books published by Prof. A. Gray is the more unique, the larger is a very creditable production, and will be valuable as a book of reference for those who desire to consult a shorter book on mathematical electricity than that of Messrs. Mascart and Joubert.

We now come now to the fourth book, "Electricity in Modern Life," by Mr. de Tunzelmann, which is written on an excellent basis, and contains a great deal of useful popular information, but it unfortunately also contains many unnecessary errors. For example, the statement on p. 11, that "a single cell of this kind," potash bichromate, "holding about a quart of solution, is capable of maintaining the light of a small incandescent lamp for some three or four hours," would rather disappoint a purchaser of a quart, or any size, bichromate cell, as he would find it most difficult to purchase an incandescent lamp that would glow with so small a difference of potential as *one* cell could produce. Again, to say in Chapter II., on "What we Know about Magnetism," "Weber's theory of magnetism may now be considered as raised from the rank of an hypothesis to that of an established fact," gives a totally wrong idea as regards our knowledge, or, rather, as regards our ignorance, of the mechanism of magnetism. "The face of the magnet that before pointed to the north," &c., is not exactly wrong; but can a face point towards anything? "If a current goes round the solenoid in the direction of the hands of a watch with its face directed towards the end from which the current flows, the end of the steel bar within the end of the solenoid at which the current leaves will be found to be a north pole and the other end a south pole," would lead the reader to imagine that the polarity of the core of an electromagnet depended partly on the direction in which the current flows *parallel* to the core, instead of depending, as is the fact, wholly on the way it flows *round* the core.

Chapter IV., on "Force, Work, and Power," is good, and the careful distinction drawn between work and power is forcible and apt. But why does the author limit the definition of a horse-power, 33,000 pounds raised 1 foot per minute, to the "indicated horse-power" of a steam-engine.

Chapter V. deals with the "Sources of Electricity." In describing the chemical action of a galvanic cell formed "of a plate of zinc and a plate of copper partly immersed in sulphuric acid," it is an obvious mistake to speak of the action as a simple liberation of hydrogen at the copper plate, and oxygen at the zinc, and to omit all reference to the formation of zinc sulphate. The first part of the following statement has been experimentally disproved some fifteen years ago:—"If either the copper or zinc is immersed alone in dilute sulphuric acid, a difference of potential will be produced between the metal and the liquid; but if the two metals are immersed side by side into the liquid, then no electrification can be detected." A galvanic battery is defined by the author as "a series of galvanic cells so arranged that the zinc of

each cell is connected with the copper of the next cell." What, then, is a collection of galvanic cells arranged in parallel, in which the zinc of every cell is connected with the zinc and not with the copper of the next? Excluding these mistakes, this chapter is fairly good; the matter, however, is rather too condensed to be intelligible to a reader not previously acquainted with the subject.

Chapter VI. deals with "Magnetic Fields," and in order to lead up to the mapping out of a magnetic field, the mapping out of the gravitation field of force in which a comet moves is first explained. But it appears to us that, since the magnetic field can be easily mapped out with iron filings in the well-known way, while the conception of a gravitation field of force is a less simple matter to grasp, Mr. de Tunzelmann has in this case explained the easy by means of the difficult.

The next chapter, on "Electrical Measurement," is quite correct, but, in view of the great difficulty that is always experienced by a beginner in grasping the idea of measuring so intangible a thing as electricity, would not this subject have been made clearer if not merely the scientific definitions of the electrical units had been given, but in addition an illustrated description of the meters used to measure amperes, volts, &c.?

Chapter VII., on "Magneto and Dynamo Electric Machines," gives a short comprehensive description of the principles of these machines, but, in order that the reader might understand what a real dynamo was like, we think it would have been better if the author had given in this chapter at least some one of the illustrations representing real dynamos which appear in other parts of this book. The symbolical figures that are given are, as the author mentions, taken from Dr. Thompson's book on dynamo machinery, and are very clear, with one exception, that while in each case the direction of the current in the wires attached to the brushes is indicated by arrows, the direction in which the wire is coiled on the armature is omitted, hence such statements as "the arrows show the current in the circuit when the armature revolves as indicated by the position of the brushes," are just as likely to be wrong as right, and tell the reader nothing. When comparing the series dynamo with the shunt dynamo, the author says that the former "will not begin to excite itself until a certain speed has been obtained depending on the resistance of the circuit." From this the reader might easily be misled into thinking that the shunt machine did not possess a similar defect. Further, he states, as "the principal objection to shunt-wound machines," that the self-induction of the field-magnet coils leads to the result that "any variation in the speed produces its effect upon the lamps before the current in the existing circuit has had time to undergo a sensible change." But, as a matter of fact, the self-induction of the field-magnet coils of a shunt machine is an *advantage*, not a *disadvantage*; for suppose that the speed increases, then the E.M.F. increases, this causes the difference of potentials between the lamp-mains to increase, which not only sends a larger current through the lamps, but also through the shunt coils. This strengthening of the field causes an additional rise in the E.M.F. of the machine, and therefore in the terminal difference of potentials. Consequently the second objectionable rise is hindered, and not accelerated, by the self-induction of the shunt coils; hence self-induction of the field-magnet coils of a shunt machine makes the difference of potentials between the lamp-mains less quickly, and not more quickly, affected by a change in the speed of driving. In speaking of alternate-current dynamos, it is stated that "in some machines the armature remains at rest, and the field-magnets are made to rotate; and in this case no sliding contact is required, the terminals of the main circuit being attached permanently to the armature." But the statement is misleading, since at least one sliding contact must *always* be used; only when the armature is fixed it is to lead the exciting current into and out of the rotating field-magnets that one, and in some cases two sliding contacts are employed.

Chapters IX., X., and XI., on "The Story of the Telegraph," "Overland Telegraphs," and on "Submarine Telegraphs," are excellent, we may almost say exciting, and they lead the reader on like the pages of a well-written novel. It is not right, however, on p. 112 to say, when speaking of telegraphing with sounders, "The dots are formed by giving a sharp stroke to the key; the dashes by depressing it more slowly," since a dash is formed not by depressing the key slowly, but by holding it down for a time when depressed. Whether a key be depressed slowly or quickly makes no difference in the signal received; what the receiver listens for is the interval between the commencement of the current produced when the key is fully depressed and its termination when the key is caused to begin to rise again. We presume that when the author says, on p. 129, "The cups" of insulators "are made of such a form as to expose the upper portions freely to the cleansing action of the rain while the lower portions are shielded from the rain so as to keep them fairly dry," he means by "upper portions" the *outside* of the cup of the insulator, and by the "lower portions" the *inside*; but if so, he has a curious way of expressing himself. The "speaking galvanometer" used in receiving the message sent through a submarine cable is not, as the author describes it on p. 150, an astatic galvanometer; and even if two magnets were employed so as to form an astatic combination, it would be quite wrong to say "each of them is attached to the back of a small mirror," since, unnecessary as it would be to use two suspended magnets in a speaking galvanometer, it would be still more useless to employ two suspended mirrors. But these are not very serious errors in chapters that are so good.

Chapters XII. and XIII., on "The Telephone" and "The Telephone Exchange System," appear to us to be too much of the newspaper special correspondent order, the descriptions in several cases being very meagre, suggestive rather than descriptive, in consequence of the author having attempted to touch on too many different things. For instance, if the photophone had to be described at all, it required more than one page and a quarter, inclusive of the illustration, to make it intelligible; in fact, unless the framework of the telephones and the gentleman's head which is between them in Fig. 53 are all composed of electrically conducting material, we fail to see how the instrument, as there depicted, works at all. Some very interesting information is given on the subject of telephone exchanges, and we should have liked to have had much more information on this electrical subject; for example, greater details regarding the switches, the reasons of the babble of many conversations that everyone hears who tries to use the telephone in London, &c.; space, if necessary, being economized by the omission of the description of the non-electrical instruments, the graphophone and phonograph.

Chapter XIV., on the "Distribution and Storage of Electrical Energy," is very good and forcible. We fail, however, to see how the use of the three-wire system leads to the result stated on p. 199, that "a variation of 5 per cent. in the E.M.F. in the mains would produce a variation of only 2½ per cent. at the lamp terminals."

The next chapter, XV., on "Electric Lighting," is also very good; "flashing" the filament of an incandescent lamp, however, does not mean sending a current through the filament while the lamp is attached to the Sprengel pump, but sending a current through the filament and making the filament incandescent when in a hydrocarbon atmosphere before it is placed inside the glass bulb of the lamp. Is it a fact that "the Shaftesbury theatre" is "now lighted by incandescent electric lamps?"

The chapter on "Electro-Motors and their Uses" is good considering how much may be said on this subject and how short a space is 14 pages to say it in. By what means, however, Messrs. Immisch have succeeded in making the dogcart for the Sultan of Turkey go "ten miles an hour for about five hours" by means of "twenty-four small accumulators which weigh about seven hundredweight" we are at a loss to conceive, since the weight of accumulators, according to our calculation, must be much greater than this in order that they may have anything like a reasonably long life.

Chapter XVII., on "Electro-Metallurgy," is interesting although very brief, but the descriptions of the electrical circuit-closers for torpedoes in the next chapter, on "Electricity in Warfare," we find too short to be intelligible. A chapter of 5 pages then follows on "Medical Electricity," and another chapter of the same length on "Miscellaneous Applications of Electricity," in which a very interesting account is given of the electrical method employed in America for protecting furnished dwelling-houses that have been left locked up during the absence of the tenants.

On closing this book one certainly cannot deny that one has had one's money's worth, even if the entertainment has been of the "variety order" so characteristic of the amusements of the present day. If a member of the general public will read the book right through, as we have done, he may perhaps feel with exultation that he has mastered the whole subject of electrical engineering; indeed, even a well-trained electrician can learn from it many things that he did not know before, concerning those branches of the subject to which he has not given special attention. But we fear that, if even a general reader were to turn up any particular subject to study in detail, he would probably wish he had been told a good deal more about what was most important, and not so much about everything electrical whether important or not. The best features of "Electricity in Modern Life" are the many interesting scientific narratives, in the writing of which Mr. de Tunzelmann appears to excel; the worst are the mistakes in the science, which more knowledge, or more care, ought to have eliminated.

ON THE TENSION OF RECENTLY FORMED LIQUID SURFACES.[1]

It has long been a mystery why a few liquids, such as solutions of soap and saponine, should stand so far in advance of others in regard to their capability of extension into large and tolerably durable laminæ. The subject was specially considered by Plateau in his valuable researches, but with results which cannot be regarded as wholly satisfactory. In his view the question is one of the ratio between capillary tension and superficial viscosity. Some of the facts adduced certainly favour a connection between the phenomena attributed to the latter property and capability of extension; but the "superficial viscosity" is not clearly defined, and itself stands in need of explanation.

It appears to me that there is much to be said in favour of the suggestion of Marangoni ("Nuovo Cimento," vols. v.–vi., 1871, p. 239), to the effect that both capability of extension and so-called superficial viscosity are due to the presence upon the body of the liquid of a coating or pellicle composed of matter whose inherent capillary force is less than that of the mass. By means of variations in this coating, Marangoni explains the indisputable fact that in vertical soap films the effective tension is different at various levels. Were the tension rigorously constant, as it is sometimes inadvertently stated to be, gravity would inevitably assert itself, and the central parts would fall 16 feet in the first second of time. By a self-acting adjustment the coating will everywhere assume such thickness as to afford the necessary tension, and thus any part of the film, considered without distinction of its various layers, is in equilibrium. There is nothing, however, to prevent the interior layers of a moderately thick film from draining down. But this motion, taking place as it were between two fixed walls, is comparatively slow, being much impeded by ordinary fluid viscosity.

In the case of soap, the formation of the pellicle is attributed by Marangoni to the action of atmospheric carbonic acid, liberating the fatty acid from its combination with alkali. On the other hand, Sondhauss (*Poggendorff's Annalen*, Ergänzungsband viii., 1878, p. 266) found that the properties of the liquid, and the films themselves, are better conserved when the atmosphere is excluded by hydrogen; and I have myself observed a rapid deterioration of very dilute solutions of oleate of soda when exposed to the air. In this case a remedy may be found in the addition of caustic potash. It is to be observed, moreover, that, as has long been known, the capillary forces are themselves quite capable of overcoming weak chemical affinities, and will operate in the direction required.

A strong argument in favour of Marangoni's theory is afforded by his observation,[1] that within very wide limits the superficial tension of soap solutions, as determined by capillary tubes, is almost independent of the strength. My purpose in this note is to put forward some new facts tending strongly to the same conclusion.

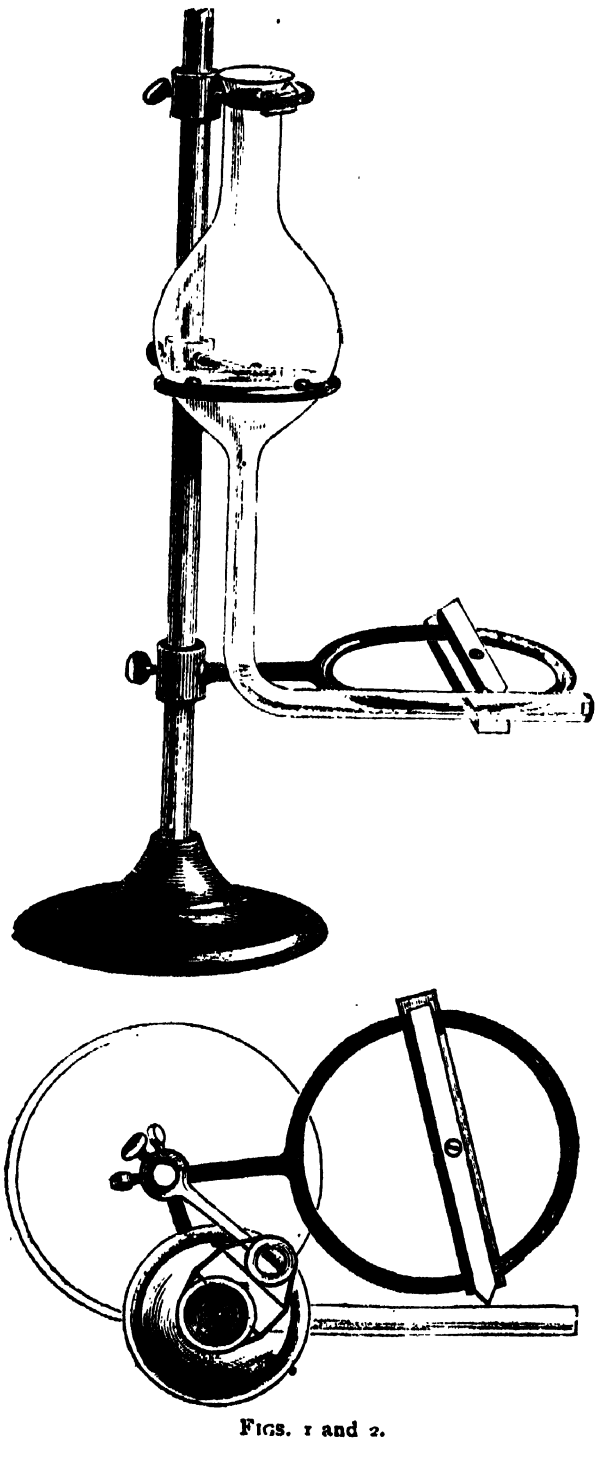
It occurred to me that, if the low tension of soap solutions as compared with pure water was due to a coating, the formation of this coating would be a matter of time, and that a test might be found in the examination of the properties of the liquid surface immediately after its formation. The experimental problem here suggested may seem difficult or impossible; but it was, in fact, solved some years ago in the course of researches upon the capillary phenomena of jets (Roy. Soc. Proc., May 15, 1879). A jet of liquid issuing under moderate pressure from an elongated, *e.g.* elliptical, aperture perforated in a thin plate, assumes a chain-like appearance, the complete period, λ, corresponding to two links of the chain, being the distance travelled over by a given part of the liquid in the time occupied by a complete transverse vibration of the column about its cylindrical configuration of equilibrium. Since the phase of vibration depends upon the time elapsed, it is always the same at the same point in space, and thus the motion is *steady* in the hydrodynamical sense, and the boundary of the jet is a fixed surface. Measurements of λ under a given head, or velocity, determine the time of vibration, and from this, when the density of the liquid and the diameter of the column are known, follows in its turn the value of the capillary tension (T) to which the vibrations are due. *Cœteris paribus*, $T \propto \lambda^{-2}$; and this relation, which is very easily proved, is all that is needed for our purpose. If we wish to see whether a moderate addition of soap alters the capillary tension of water, we have only to compare the wave-lengths λ in the two cases, using the same aperture and head. By this method the liquid surface may be tested before it is $\frac{1}{100}$ second old.

Since it was necessary to be able to work with moderate quantities of liquid, the elliptical aperture had to be rather fine, about 2 mm. by 1 mm. The reservoir was an ordinary flask, 8 cm. in diameter, to which was sealed below as a prolongation a (1 cm.) tube bent at right angles (Figs. 1, 2). The aperture was perforated in thin sheet brass, attached to the tube by cement. It was about 15 cm. below the mark, near the middle of the flask, which defined the position of the free surface at the time of observation.

[1] A Paper read by Lord Rayleigh, Sec.R.S., before the Royal Society, on March 6.

[1] *Poggendorff's Annalen*, vol. cxliii., 1871, p. 342. The original pamphlet dates from 1865.

The arrangement for bringing the apparatus to a fixed position, designed upon the principles laid down by Sir W. Thomson, was simple and effective. The body of the flask rested ont hree protuberances from the ring of a retort stand, while the neck was held by an india-rubber band into a V-groove attached to an upper ring. This provided five contacts. The necessary sixth contact was effected by rotating the apparatus about its vertical axis until the delivery tube bore against a stop situated] near its free end. The flask could thus be



Figs. 1 and 2.

removed for cleaning without interfering with the comparability of various experiments.

The measurements, which usually embrace two complete periods, could be taken pretty accurately by a pair of compasses with the assistance of a magnifying glass. But the double period was somewhat small (16 mm.), and the little latitude admissible in respect to the time of observation was rather embarrassing. It was thus a great improvement to take magnified photographs of the jet, upon which measurements could afterwards be made at leisure. In some preliminary experiments the image upon the ground glass of the camera was utilized without actual photography. Even thus a decided advantage was realized in comparison with the direct measurements.

Sufficient illumination was afforded by a candle flame situated a few inches behind the jet. This was diffused by the interposition of a piece of ground glass. The lens was a rapid portrait lens of large aperture, and the ten seconds needed to produce a suitable impression upon the gelatine plate was not so long as to entail any important change in the condition of the jet. Otherwise, it would have been easy to reduce the exposure by the introduction of a condenser. In all cases the sharpness of the resulting photographs is evidence that the sixth contact was properly made, and thus that the scale of magnification was strictly preserved. Fig. 3 is a reproduction on the original scale of a photograph of a water-jet taken upon November 9. The distance recorded as 2λ is between the points marked A and B, and was of course measured upon the original negative. On each occasion when various liquids were under investigation, the photography of the water-jet was repeated, and the results agreed well.

After these explanations it will suffice to summarise the actual measurements upon oleate of soda in tabular form. The standard solution contained 1 part of oleate in 40 parts of water, and was diluted as occasion required.[1] All lengths are given in millimetres.

	Water.	Oleate 1/40.	Oleate 1/80.	Oleate 1/400.	Oleate 1/4000.
2λ	40·0	45·5	44·0	39·0	39·0
h	31·5	11·0	11·0	11·0	23·0

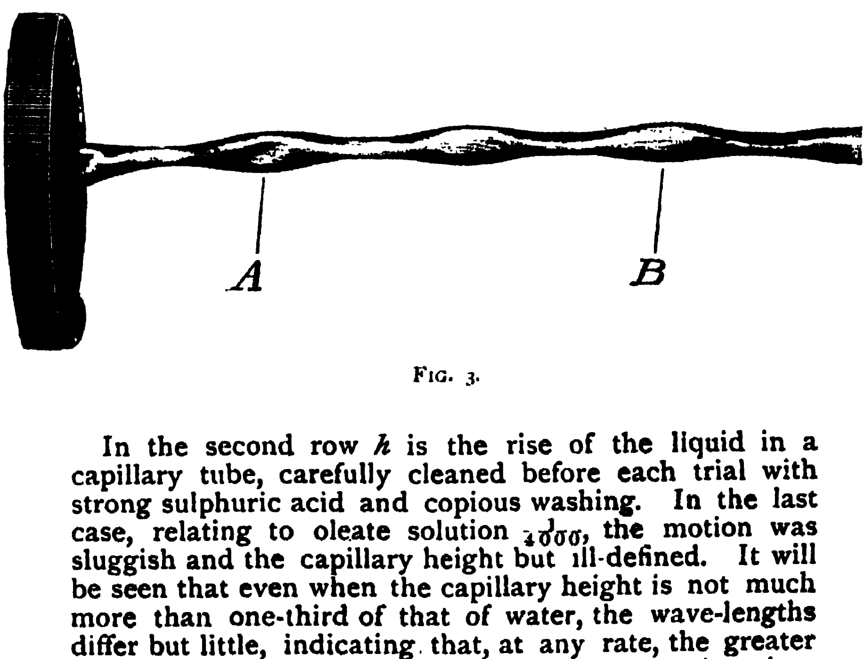


Fig. 3.

In the second row h is the rise of the liquid in a capillary tube, carefully cleaned before each trial with strong sulphuric acid and copious washing. In the last case, relating to oleate solution $\frac{1}{4000}$, the motion was sluggish and the capillary height but ill-defined. It will be seen that even when the capillary height is not much more than one-third of that of water, the wave-lengths differ but little, indicating that, at any rate, the greater part of the lowering of tension due to oleate requires time for its development. According to the law given above, the ratio of tensions of the newly-formed surfaces for water and oleate ($\frac{1}{80}$) would be merely as 6 : 5.[2]

Whether the slight differences still apparent in the case of the stronger solutions are due to the formation of a sensible coating in less than $\frac{1}{100}$ second, cannot be absolutely decided; but the probability appears to lie in the negative. No distinct differences could be detected between the first and second wave-lengths; but this observation is, perhaps, not accurate enough to settle the question. It is possible that a coating may be formed on the surface of the glass and metal, and that this is afterwards carried forward.

[1] Although I can find no note of the fact, I think I am right in saying that large bubbles could be blown with the weakest of the solutions experimented upon.

[2] Curiously enough, I find it already recorded in my note-book of 1879, that λ is not influenced by the addition to water of soap sufficient to render impossible the rebound of colliding jets.

As a check upon the method, I thought it desirable to apply it to the comparison of pure water and dilute alcohol, choosing for the latter a mixture of 10 parts by volume of strong (not methylated) alcohol with 90 parts water. The results were as follows:—

$$2\lambda \text{ (water)} = 38 \cdot 5, \qquad 2\lambda \text{ (alcohol)} = 46 \cdot 5,$$
$$h \text{ (water)} = 30 \cdot 0, \qquad h \text{ (alcohol)} = 22 \cdot 0;$$

but it may be observed that they are not quite comparable with the preceding for various reasons, such as displacements of apparatus and changes of temperature. It is scarcely worth while to attempt an elaborate reduction of these numbers, taking into account the differences of specific gravity in the two cases; for, as was shown in the former paper, the observed values of λ are complicated by the departure of the vibrations from isochronism, when, as in the present experiments, the deviation from the circular section is moderately great. We have—

$$(46 \cdot 5/38 \cdot 5)^2 = 1 \cdot 46, \qquad 30/22 = 1 \cdot 36;$$

and these numbers prove, at any rate, that the method of wave-lengths is fully competent to show a change in tension, provided that the change really occurs at the first moment of the formation of the free surface.

In view of the great extensibility of saponine films it seemed important to make experiments upon this material also. The liquid employed was an infusion of horse chestnuts of specific gravity 1·02, and, doubtless, contained other ingredients as well as saponine. It was capable of giving large bubbles, even when considerably diluted (6 times) with water. Photographs taken on November 23 gave the following results:—

$$2\lambda \text{ (water)} = 39 \cdot 2, \qquad 2\lambda \text{ (saponine)} = 39 \cdot 5,$$
$$h \text{ (water)} = 30 \cdot 5, \qquad h \text{ (saponine)} = 20 \cdot 7.$$

Thus, although the capillary heights differ considerably, the tensions at the first moment are almost equal. In this case then, as in that of soap, there is strong evidence that the lowered tension is the result of the formation of a pellicle.

Though not immediately connected with the principal subject of this communication, it may be well here to record that I find saponine to have no effect inimical to the rebound after mutual collision of jets containing it. The same may be said of gelatine, whose solutions froth strongly. On the other hand, a very little soap or oleate usually renders such rebound impossible, but this effect appears to depend upon *undissolved* greasy matter. At least the drops from a nearly vertical fountain of *clear* solution of soap were found not to scatter (Roy. Soc. Proc., June 15, 1882). The rebound of *jets* is, however, a far more delicate test than that of *drops*. A fountain of strong saponine differs in appearance from one of water; but this effect is due rather to the superficial viscosity, which retards, or altogether prevents, the resolution into drops.

The failure of rebound when jets or drops containing milk or undissolved soap come into collision has not been fully explained; but it is probably connected with the disturbance which must arise when a particle of grease from the interior reaches the surface of one of the liquid masses.

P.S.—I have lately found that the high tension of recently formed surfaces of soapy water was deduced by A. Dupré ("Théorie Mécanique de la Chaleur," Paris, 1869), as long ago as 1869, from some experiments upon the vertical rise of fine jets. Although this method is less direct than that of the present paper, M. Dupré must be considered, I think, to have made out his case. It is remarkable that so interesting an observation should not have attracted more attention.

NOTES.

It is stated that the committee to be appointed to inquire into colour-blindness in seamen, railway guards, and others, will not be exclusively confined to members of the Royal Society. Some gentlemen who, like Dr. Farquharson, M.P., and Mr. Bickerton, of Liverpool, have taken special interest in the question will, it is said, be asked to join the committee. A further question on the subject will, in the course of a few days, be put to the President of the Board of Trade.

We regret to have to record the death of Sir John Henry Lefroy, F.R.S. He died on Friday evening last at his residence, Lewarne, a few miles from Liskeard. He was seventy-three years of age. He entered the Royal Artillery in 1834, and was Director of the Magnetical and Meteorological Observatory at St. Helena from 1840 to 1841, whence he moved to a similar position at Toronto in 1842. During the next year he made a magnetic survey of the interior of North America from Montreal to the Arctic Circle. From 1854 to 1855 he was scientific adviser to the Duke of Newcastle at the War Office on subjects of artillery and inventions, and in 1855 he was sent, as lieutenant-colonel, on a special mission to the seat of war. Afterwards he held several high military appointments. In 1882 he was made a general, and retired. He had been elected a Fellow of the Royal Society in 1848.

Mr. Thomas Johnson, Demonstrator in Botany at the Normal School of Science and Royal School of Mines, has been appointed to succeed the late Prof. McNab, as Professor of Botany at the Royal College of Science, Dublin. Prof. Johnson begins lecturing this term.

An International Medical Congress was opened at Vienna on Tuesday, and will continue its sittings until to-morrow (Friday). Many physicians from the principal Europe an countries are taking part in the proceedings.

At the next meeting of the Anthropological Institute, on Tuesday, April 22, M. Jacques Bertillon will give a lecture, with demonstrations, on the method now practised in France of identifying criminals by comparing their measures with those of convicted persons in the prison registers. The registers contain the measures of many tens of thousands of persons, with their photographs; yet M. Bertillon's method enables the reference to be rapidly effected. It is thought, therefore, that the authorities in England who are concerned with the police, or with the identification of deserters from the army or the navy, may be glad of the opportunity of hearing M. Bertillon's exposition.

The Meteorological Office has adopted a new way of spreading information as to the condition of the weather on our coasts. On Monday it began to exhibit, at 63 Victoria Street, Westminster, outside the building, a series of boards, showing the state of the wind, weather, and sea at Yarmouth, Dover, the Needles, Scilly, Valentia (Ireland), and Holyhead. The information given is for 8 o'clock in the morning and 2 o'clock in the afternoon, and the notices are posted up at about 9.30 a.m. and 3 p.m. respectively. The words are printed in clear type, and can be read by those having ordinarily good sight from the pavement or roadway.

At the meeting of the Institution of Civil Engineers on Tuesday evening, Sir Frederick Bramwell read a paper on the application of electricity to welding, stamping, and other cognate purposes.

There has been some talk lately about a scheme for the construction of a bridge across the Bosphorus. The Turkish newspaper *Hakikat* gives some particulars of the project *à propos* of

an offer by a French syndicate to build a bridge of 800 metres in length and 70 metres high between Roumeli and Anatol. Hissar. The bridge would consist of one span, and this would exceed in length by one-half the longest span of the Forth Bridge. The Anatolian railway, it is thought, will make the construction of such a bridge a necessary and feasible undertaking before many years.

MADAME ROSA KIRSCHBAUM, who has taken the degree of Doctor of Medicine at a Swiss University, has been authorized by a special imperial decree to conduct a hospital for eye diseases at Salzburg. The Vienna Correspondent of the *Times* says this is the first case of a lady physician being admitted to medical practice in Austria.

THE new number of the *Kew Bulletin* begins with a section on canaigre, the root of which seems likely to take an important place as a tanning material. This is followed by sections on pistachio cultivation in Cyprus, Indian sugar, and mites on sugar-cane. The section on Indian sugar consists chiefly of a selection from a file of documents sent to Kew from the India Office, containing much valuable information as to the production of cane sugar in India.

AT the meeting of the Scientific Committee of the Royal Horticultural Society on April 8, Mr. Wilson exhibited a plant of a primrose, a seedling from Scott Wilson, showing a greater advance to a deep blue colour thanh as yet been made. A series of intermediate forms were also shown.

THE Prefect of Savoy has recently prohibited the gathering of the *Cyclamen* in the woods of his department. Notwithstanding its abundance in the locality, this beautiful plant had been threatened with total extinction, from the enormous numbers gathered each year for sale in the markets of Chambéry and Aix-les-Bains.

A SINGULAR fact is related by M. Lagatu in the *Feuille des Jeunes Naturalistes*. In the year 1884 a large number of cattle died after having browsed in a particular pasture in the department of l'Oise. M. E. Prillieux found the cause of death to be poisoning by ergotized *Lolium*; and he attributes it to the fact that the cattle were sent to the pasture about 10 days later than usual. M. Prillieux frequently found ergot on tufts of grass refused by the cattle, which marked the spots where dejecta had been left without being scattered.

DR. G. B. DE TONI has retired from the editorship of the Italian bi-monthly journal *Notarisia*, devoted to cryptogamic botany, which will in future be conducted by Dr. David Levi Morenos.

AT the last meeting of the Natural History Society of Kiel, Major Reinhold read a paper on the botanical condition of the German Ocean. According to researches recently made, the eastern part is almost wholly bare of vegetation. This is believed to be owing to the strong tidal currents, which so disturb the sea bottom as to prevent the germs and spores of marine plants from settling.

A ZOOLOGICAL floating station is now in working order at Isefiord on the Danish coast, under the direction of Dr. Petersen.

THE Proceedings of the International Congress of Zoology, held last August in Paris, were issued a few days ago. Among the contributors are Messrs. Bogdanow, Bowdler Sharpe, D'Arcy Thompson, E. P. Wright, C. V. Riley, V. Wagner, Ray Lankester, A. S. Packard, Trimen, Rütimeyer, Retzius, Hubrecht, de Selys-Longchamps, Agassiz, Blanford, L. Netto, W. A. Conklin, A. Fritsch, and McLachlan. This list of names suffices to show that the meeting was really of an international character.

A SHOCK of earthquake was felt in M U.S.A., on April 11.

REPORTS of an earthquake felt on March 26, between 9.15 and 9.20 p.m., have been received from Innsbruck, the Ziller Valley, Sterzing, Bozen, Meran, the Puster Valley, Salurn, Arco, Ampezzo, and the Weiten Valley. The direction of the shocks was from north to south.

Two papers on "The Cradle of the Semites," read before the Philadelphia Oriental Club, have just been published. The first is by Dr. Daniel G. Brinton, who contends that the Semitic stock came originally from "those picturesque valleys of the Atlas which look forth toward the Great Ocean and the setting sun." Prof. Jastrow, the author of the second paper, agrees generally as to the probability of a Semitic migration from Africa into Asia, but thinks that Dr. Brinton goes farther than the evidence warrants when he tries to indicate the particular region of Africa from which the migration started.

DURING the summer and autumn of 1888, and the following winter, Mr. Albert Koebele carried on researches in Australia for the purpose of determining whether it would not be possible to introduce into California the most efficient of the Australian natural enemies of the fluted scale (*Icerya purchasi*, Maskell). A report on his investigations has just been issued by the U.S. Department of Agriculture; and from this it seems that the results achieved by him are highly satisfactory. Prof. Riley, who contributes an introduction to the report, says that one of the insects imported, the Cardinal Vedalia (*Vedalia cardinalis*, Mulsant), has multiplied and increased to such an extent as to rid many of the orange-groves of Icerya, and to promise immunity in the near future for the entire State of California.

SOME interesting notes on the archæology and ethnology of Easter Island, by Mr. Walter Hough, appear in the new number of the *American Naturalist*. One of the last acts of the late Prof. Spencer F. Baird was to induce the American Navy Department to send a vessel to explore the island and bring back representative specimens. The U.S.S. *Mohican*, then at Tahiti, was detailed, and the fruits of the successful twelve days' exploration are now to be seen in the north and west halls of the American National Museum. They consist of several stone images, carved stones, painted slabs, and a fine collection of smaller objects obtained by Paymaster W. J. Thomson, U.S.N. In his article Mr. Hough makes good use of the materials thus brought together, and of information placed at the disposal of the National Museum by Mr. Thomson, and by Surgeon G. H. Cooke, U.S.N.

Two interesting papers on primitive architecture, by Mr. Barr Ferree, have been reprinted together, one from the *American Naturalist*, the other from the *American Anthropologist*. In the first article the author deals with sociological influences, in the second with climatic influences.

FROM the reports, for the past official year, of the Directors of Public Instruction and their subordinates in various Indian districts, on vernacular literature, it appears that, on the whole, but very little scientific work of an original character is being performed by natives of India, and that the taste for scientific literature, original or translated, can scarcely be said to exist. In Bengal, the Director says that, "while physiology keeps in old grooves, medicine seems to be trying to return to them." In Madras scientific works appear to have been confined to the translation of an old Sanskrit work on medicine, unless indeed a collection of a thousand stanzas in Tamil verse, treating of the Yoga philosophy, can be called scientific." In the North-West Provinces eleven works on medicine were registered during the year, some of them being translations, while others are described as original works of some merit. The great mass of Indian literature appears to be composed of fiction, poetry, and the

drama, and, in Bengal especially, is described as for the most part worthless and immoral.

IT is well known that a connection has been observed (in Munich and other towns) between ground-water and typhus; the disease gaining force as the water goes down, and declining as the water rises. (It is thought that certain decompositions are favoured by air taking the place of water in the ground.) While in former years Hamburg has exemplified this effect, the last typhus epidemic there, according to Prof. Brückner, was quite in discordance with the variations of ground-water. From 1838, it is stated, the typhus mortality in Hamburg steadily fell from 19 to 2 or 3 per 1000; but from 1885 it rose again to 9; and whereas before 1885 the epidemic was a summer one, with its maximum in August, it now became a winter one, with maximum in December. The curve of ground-water continued to have the same course as before. Prof. Brückner points out that this epidemic of 1884–87 corresponded in time with certain harbour works being carried out at Hamburg, and he attributes it to the upturning of enormous masses of earth, the abode of numberless bacteria, whose diffusion among the inhabitants was thus facilitated.

THE volume of Results of the Magnetical and Meteorological Observations made at the Royal Observatory, Greenwich, in the year 1887, contains an appendix of considerable importance to meteorologists, viz. the hourly reduction of the photographic records of the barometer for 1874–76, and of the dry and wet bulb thermometers for 1869–76. This appendix, which is also published separately, continues the results for the twenty years published in 1878. The tables now given complete the reduction of the photographic records nearly to the present time, commencing with the year 1854 for the barometer, and with the year 1849 for the thermometers. The means for the two periods are given separately, but their value would be further enhanced if the results for the whole period were also given in a combined form.

WITH the month of January, the Monthly Weather Review of the United States Signal Service entered upon its eighteenth year of publication. The Review is based upon reports from 1934 observers, a large majority of whom belong to the State Weather Services. This number is exclusive of the reports which are usually supplied by the Central Pacific Railway Company, but which could not be forwarded for January, owing to snow blockades and floods. One hundred and twenty miles of the railroad crossing the Sierra Nevada range of mountains was blockaded by snow, being the heaviest blockade ever known there, and it is estimated that fully 50 per cent. of the live stock was lost from exposure and starvation. The paths of twelve depressions that appeared over the North Atlantic Ocean are plotted on a chart. Of the nine depressions that moved eastwards from the American continent, four were traced to the British Isles. Three storms first appeared over the ocean, and two of these were also traced to the British Isles. Among the "Notes and Extracts" is an article on the recent comparison of anemometers, by Prof. Marvin. The results obtained show that of the anemometers exposed to the same wind, those with short arms gave a lower velocity than those with long arms. No experiments were made beyond 32 miles per hour, and although various formulæ were given for the reduction of wind velocities, Prof. Marvin states that they cannot be depended on for velocities beyond the experimental values, so that much more information has yet to be gained, as to the action of anemometers with high velocities, from careful experiments with whirling machines. We take this opportunity of pointing out that a general subject-index to the Monthly Weather Reviews and the Annual Reports of the Chief Signal Officer, to 1887, has been published, and affords easy reference to the valuable information contained in these publications.

A RECENT writer in the *North China Herald* of Shanghai says that the climate of Asia is becoming colder than it formerly was, and its tropical animals and plants are retreating southwards at a slow rate. This is true of China, and it is also the case in Western Asia. The elephant in a wild state was hunted in the eighth century B.C. by Tiglath Pileser, the King of Assyria, near Carchemish, which lay near the Euphrates in Syria. Four or five centuries before this Thothmes III., King of Egypt, hunted the same animal near Aleppo. In high antiquity the elephant and rhinoceros were known to the Chinese, they had names for them, and their tusks and horns were valued. South China has a very warm climate which melts insensibly into that of Cochin-China, so that the animals of the Indo-Chinese peninsula would, if there were a secular cooling of climate, retreat gradually to the south. This is just what seems to have taken place. In the time of Confucius elephants were in use for the army on the Yangtze River. A hundred and fifty years after this, Mencius speaks of the tiger, the leopard, the rhinoceros, and the elephant, as having been, in many parts of the empire, driven away from the neighbourhood of the Chinese inhabitants by the founders of the Chou dynasty. Tigers and leopards are not yet by any means extinct in China. The elephant and rhinoceros are again spoken of in the first century of our era. If to these particulars regarding elephants be added the retreat from the rivers of South China of the ferocious alligators that formerly infested them, the change in the fauna of China certainly seems to show that the climate is much less favourable for tropical animals than it formerly was. In fact it appears to have become drier and colder. The water buffalo still lives, and is an extremely useful domestic animal, all along the Yangtze and south of it, but is not seen north of the old Yellow River in the province of Kiangsu. The Chinese alligator is still found in the Yangtze, but so rare is its appearance that foreign residents in China knew nothing about it till it was described by M. Fauvel. The flora is also affected by the increasing coldness of the climate in China. The bamboo is still grown in Peking with the aid of good shelter, moisture, and favourable soil, but it is not found naturally growing into forest in North China, as was its habit two thousand years ago. It grows now in that part of the empire as a sort o garden plant only. It is in Szechuan province that the southern flora reaches farthest to the northward.

SOME interesting experiments on the physiology of sponges have been recently made by Dr. Lendenfeld, of Innsbruck (*Humboldt*). He operated with eighteen different species, putting carmine, starch, or milk, in the water of the aquarium, and also trying the effect of various poisons—morphine, strychnine, &c. The following are some of his results: Absorption of food does not take place at the outer surface, but in the interior; only foreign substances used for building up the skeleton enter the sponge without passing into the canal-system. Grains of carmine and other matters often adhere to the flat cells of the canals, but true absorption only takes place in the ciliated cylindrical cells of the ciliated chamber. These get quite filled with carmine grains or milk spherules, but starch grains prove too large for them. Remaining in these cells a few days, the carmine cells are then ejected; while milk particles are partly digested, and then passed on to the migratory cells of the intermediate layer. Any carmine particles found in these latter cells have entered accidentally through external lesions. The sponge contracts its pores when poisons are put in the water; and the action is very like that of poisons on muscles of the higher animals. Especially remarkable is the cramp of sponges under strychnine; and the lethargy (to other stimuli) of sponges treated with cocain. As these poisons, in the higher animals, act indirectly on the muscles through the nerves, it seems not without warrant to suppose that sponges also have nerve-cells which cause muscular contraction.

THE additions to the Zoological Society's Gardens during the past week include a Black-eared Marmoset (*Hapale penicillata*) from South-east Brazil, presented by Mr. J. A. Watson, F.Z.S a Lesser White-nosed Monkey (*Cercopithecus petaurista* ♀) from West Africa, presented by Mr. E. B. Parfitt; a Macaque Monkey (*Macacus cynomolgus* ♀) from India, presented by Mrs. H. F. Batt; a Sambur Deer (*Cervus aristotelis* ♂) from India, presented by Capt. George James; a Common Badger (*Meles taxus*, white variety), British, presented by the Hon. Morton North; a Jackdaw (*Corvus monedula*), British, presented by Mrs. Bowden; a Blessbok (*Alcelaphus albifrons* ♂) from South Africa, four Undulated Grass Parrakeets (*Melopsittacus undulatus* 2 ♂ 2 ♀) from Australia, deposited; an Australian Crane (*Grus australasiana*), two Chestnut-eared Finches (*Amadina castanotis*) from Australia, three European Flamingoes (*Phœnicopterus antiquorum*), four Great Bustards (*Otis tarda*), European, purchased.

OUR ASTRONOMICAL COLUMN.

OBJECTS FOR THE SPECTROSCOPE.

Sidereal Time at Greenwich at 10 p.m. on April 17 = 11h. 43m. 55s.

Name.	Mag.	Colour.	R.A. 1890.	Decl. 1890.

(6) U Virginis	Var.	Reddish.	12 45 31	− 6 9

Remarks.

(1) This large white nebula is situated in the constellation of Ursa Major, and is thus described in the General Catalogue:—"Very bright, very large, suddenly brighter in the middle to a nucleus." According to Smyth, it is oval in shape, the lateral edges being better defined than the ends. Lord Rosse's telescope s' owed it to be much mottled. In 1866 Dr. Huggins described its spectrum as continuous, with "a suspicion of unusual brightness about the middle part." No observations of the spectrum appear to have been made since then, but it is important that it should be re-examined. The spectra of the white nebulæ are usually almost entirely wanting in red light, and it is therefore quite possible that the brightening in the middle is nothing more than the green carbon fluting near λ517. Direct comparisons with the spectrum of a spirit-lamp flame would soon decide this point. In any case, if there be one or more brightenings, some attempt should be made to determine their positions.

(2) The spectrum of this star has not yet been completely described. Secchi stated that it was of the type of α Orionis, and Dunér states that it is most probably a star of Group II., but very feebly developed. As I have previously pointed out, it is these "feebly developed" stars of Group II. which require further examination rather than those which are described as "fully developed," as they are probably transition stages between Groups I. and II., or Groups II. and III.

(3) According to Konkoly, this star has a well-developed spectrum of the solar type. Differential observations as to whether the star belongs to Group III. or to Group V. are required. (For criteria so far determined, see p. 20.)

(4) The spectrum of this star is a very fine one of Group IV. The usual observations are required.

(5) D'Arrest and Dunér both describe the spectrum of this star as a magnificent one of Group VI. According to Dunér, the principal bands are very dark, and the subsidiary bands 4 and 5 are well visible, while the bands 1, 2, 3 are very weak. He also states that the spectrum is rendered unique by the fact that the least refrangible part of the sub-zone in the yellow is considerably weaker than the other. Further observations, as previously suggested for similar stars, should be made.

(6) This star affords another opportunity of searching for bright lines in the spectrum of a variable of Group II. near maximum. Vogel states that the spectrum is a fine one of Group II., but we have as yet no detailed description of the bands present. The period of the variable is about 207 days, and it ranges in magnitude from 7·7–8·1 at maximum to 12·2–12·8 at minimum. The maximum will occur on April 21, but as Mr. Espin has noticed that the bright lines sometimes do not appear until after the maximum, it will be desirable to continue the observations for some days after. The variations of the bright carbon flutings should also receive attention.

A. FOWLER.

COMET BROOKS (*a* 1890).—The following elements have been computed by Dr. Bidschof, of the Imperial Observatory, Vienna, from observations at Cambridge, U.S., March 21; Vienna, March 4 and 28 (*Astr. Nach.*, No. 2962):—

T = 1890 June 3·6399 Berlin mean time.

$$\left.\begin{aligned} \omega &= 71^\circ\ 7'\!\cdot\!5 \\ \Omega &= 320\ 44\cdot9 \\ \iota &= 121\ 17\cdot2 \end{aligned}\right\} \text{Mean Eq. 1890·0.}$$

$\log q = 0\cdot27189$

Ephemeris for Berlin Midnight.

NEW VARIABLE IN CÆLUM.—Prof. Pickering, in a communication to *Astr. Nach.*, No. 2962, notes that an examination of a plate taken by Mr. S. J. Bailey at the Closica station in Peru, shows that the G and *h* lines of hydrogen are bright in the spectrum of a star whose position for 1875 is R.A. 4h. 36·2m., Decl. − 38° 29′. An inspection of photographic chart plates indicates that the star is variable, and its spectrum seems to place it in the same class as *o* Ceti, R Hydrae, R Leonis, and other long-period variables. The date on which the plate was taken is not given, but it is observed that the spectrum is as bright photographically as that of Cordoba Catalogue No. 1077, which is of the magnitude 7½, and since the former is a red star, it was probably much brighter visually. Eye observations at Cambridge, U.S., on February 20 and 21 of this year show that the star was then about magnitude 10·5. It seems, therefore, that the bright lines of hydrogen were photographed in the spectrum of this object when it was near a maximum.

GEOGRAPHICAL NOTES.

THE Council of the Royal Geographical Society met on Monday, and finally decided upon the awards of the honours for the year. One of the Royal Medals has been awarded to Emin Pasha, in recognition of the services rendered by him to geography and the allied sciences by his explorations and researches in the countries east, west, and south of the Upper Nile during his administration of the Equatorial Province of Egypt. The other Royal Medal has been awarded to Lieut. F. E. Younghusband, for his journey across Central Asia in 1886–87, from Manchuria and Pekin *viâ* Hami and Kashgar, and over the Mushtagh to Cashmere and India, a distance of 7000 miles. The Cuthbert Peek grant has been awarded to Mr. E. C. Hare for his observations on the physical geography of Tanganyika made during his many years' residence on that lake. The Murchison grant has been awarded to Signor Vittoria Sella, in consideration of his recent journey in the Caucasus, and the advance made in our knowledge of the physical characteristics and the topography of the chain by means of his series of panoramic photographs taken above the snow level. The Gill

memorial has been given to Mr. C. M. Woodford, for his three expeditions to the Solomon Islands, and the additions made by him to our topographical knowledge and the natural history of the islands. The new honorary corresponding members are Prof. Davidson, of San Francisco; Dr. Junker, the friend of Emin Pasha, and Central African explorer; and Senhor Santa Anna Nery, of Rio Janeiro.

AT the evening meeting of the Royal Geographical Society on Monday, Sir M. E. Grant Duff in the chair, Dr. Hans Meyer read a paper on his journey to the summit of Kilima-Njaro. After giving a short account of his expedition in 1887, and the discouragements to which he had been subjected on two subsequent efforts to carry out his programme, Dr. Meyer proceeded to say that, while the main portion of the caravan encamped in Marangu, he ascended with Herr Purtscheller and eight picked men through the primæval forest to a stream beyond, where he had encamped in the year 1887, at an altitude of 9200 feet. There their large tent was pitched, straw huts were built for the men, and firewood collected. Accompanied by four men they travelled for two more days up the broad, grassy, southern slopes of Kilima-Njaro to the fields of rapilli on the plateau between Kibo and Mawenzi, and found there to the south-east of Kibo, under the protection fforded by some blocks of lava, a spot, at an altitude of 14,270 feet, well suited for the erection of their small tent. As soon as the instruments and apparatus had been placed under cover, three of the men returned to the camp on the edge of the forest, and only one, a Pangani negro, Mwini Amani by name, remained to share, uncomplainingly, their sixteen days' sojourn on the cold and barren heights. With regard to their maintenance, it had been arranged that every third day four men should come up with provisions from the lower camp in Marangu to the central station on the edge of the forest, and that two of the men stationed there should thence convey the necessary food to them in the upper camp, returning immediately afterwards to their respective starting-places. And this accordingly was done. Firewood was supplied by the roots of the low bushes still growing there in a few localities, and their negro fetched a daily supply of water from a spring rising below the camp. In that manner they were enabled, as if from an Alpine Club hut, to carry out a settled programme in the ascent and surveying of the upper heights of Kilima-Njaro. The ice-crowned Kibo towered up steeply another 5000 feet to the west of their camp, itself at an altitude of 14,300 feet. On October 3 they undertook their first ascent. The previous day they had resolved to make the first attempt, not in the direction chosen by him in 1887, but up a large rib of lava which jutted out to the south-east, and formed the southern boundary of the deepest of the eroded ravines on that side of the mountain. Their simple plan of operations, which they succeeded in carrying out, was to climb up this lava-ridge to the snow-line, to begin from its uppermost tongue the scramble over the mantle of ice, and endeavour to reach by the shortest way the peak to the south of the mountain, which appeared to be the highest point. It was not till half-past 7 o'clock that they reached the crown of that rib of lava which had been their goal from the very first, and, panting for breath, they began to pick their way over the boulders and *débris* covering the steep incline of the ridge. Every ten minutes they had to pause for a few moments to give their lungs and beating hearts a short breathing space, for they had now for some time been above the height of Mont Blanc, and the increasing rarefaction of the atmosphere was making itself gradually felt. At an altitude of 17,220 feet they rested for half an hour; apparently they had attained an elevation superior to the highest point of Mawenzi, which the rays of the morning sun were painting a ruddy brown. Below them, like so many mole-heaps, lay the hillocks rising from the middle of the saddle. A few roseate cumulus clouds floated far over the plain, reflecting the reddish-brown laterite soil of the steppe; the lowlands, however, were but dimly visible through the haze of rising vapour. The ice-cap of Kibo was gleaming above their heads, appearing to be almost within reach. Shortly before 10 o'clock they stood at its base, at an elevation of 18,270 feet above sea-level. At that point the face of the ice did not ascend, but almost immediately afterwards it rose at an angle of 35°, so that, without ice-axes, it would have been absolutely impracticable. The toilsome work of cutting steps in the ice began about half-past 10; slowly they progressed by the aid of the Alpine rope, the brittle and slippery ice necessitating every precaution. They made their way across the crevices of one of the glaciers that projected downwards into the valley which they had traversed in the early morning, and took a rest under the shadow of an extremely steep protuberance of the ice-wall at an altitude of 19,000 feet. On recommencing the ascent the difficulty of breathing became so pronounced that every fifty paces they had to halt for a few seconds, bending their bodies forward and gasping for breath. The oxygen of the air amounted there, at an elevation of 19,000 feet, to only 40 per cent., and the humidity to 15 per cent. of what it was at sea level. No wonder that their lungs had such hard work to do. The surface of the ice became increasingly corroded; more and more it took the form which Güssfeldt, speaking of Aconcagua, in Chili, called *nieve penitente*. Honeycombed to a depth of over 6 feet, in the form of rills, teeth, fissures, and pinnacles, the ice-field presented the foot of the mountaineer with difficulties akin to that of a "Karrenfeld." They frequently broke through as far as their breasts, causing their strength to diminish with alarming rapidity. And still the highest ridge of ice appeared to be as distant as ever. At last, about 2 o'clock, after eleven hours' climb, they drew near the summit of the ridge. A few more hasty steps in the most eager anticipation, and then the secret of Kibo lay unveiled before them. Taking in the whole of Upper Kibo, the precipitous walls of a gigantic crater yawned beneath them. The first glance told that the most lofty elevation of Kibo lay to their left, on the southern brim of the crater, and consisted of three pinnacles of rock rising a few feet above the southern slopes of the mantle of ice. They first reached the summit on October 6, after passing the night below the limits of the ice, in a spot sheltered by overhanging rocks, at an altitude of 15,160 feet, an elevation corresponding to that of the summit of Monte Rosa. Wrapped up in their skin bags, they sustained with tolerable comfort even the minimum temperature of 12° F., experienced during the night, and were enabled, about 3 o'clock in the morning of October 6, to start with fresh energy on their difficult enterprise of climbing the summit; and this time Njaro, the spirit of the ice-crowned mountain, was gracious to them—they reached their goal. At a quarter to 9 they were already standing on the upper edge of the crater, at the spot from which they had retraced their steps on October 3. Their further progress, from this point to the southern brim of the crater, although not easy, did not present any extraordinary difficulty. An hour and a half's further ascent brought them to the foot of the three highest pinnacles, which they calmly and systematically climbed one after another. Although the state of the atmosphere and the physical strain of exertion remained the same as on the previous ascent, yet this time they felt far less exhausted, because their condition morally was so much more favourable. The central pinnacle reached a height of about 19,700 feet, overtopping the others by 50 to 60 feet. He was the first to tread, at half-past 10 in the morning, the culminating peak. He planted a small German flag, which he had brought with him in his knapsack, upon the rugged lava summit, and christened that—the loftiest spot in Africa—Kaiser Wilhelm's Peak. After having completed the necessary measurements, they were free to devote their attention to the crater of Kibo, of which an especially fine view was obtainable from Kaiser Wilhelm's Peak. The diameter of the crater measured about 6500 feet, and it sank down some 600 feet in depth. In the southern portion the walls of lava were either of an ash-grey or reddish-brown colour, and were entirely free from ice, descending almost perpendicularly to the base of the crater; and in its northern half the ice sloped downwards from the upper brim of the crater in terraces, forming blue and white galleries of varying steepness. A rounded cone of eruption, composed of brown ashes and lava, rose in the northern portion of the crater to a height of about 500 feet, which was partly covered by the more than usually thick sheet of ice extending from the northern brim of the crater. The large crater opened westwards in a wide cleft, through which the melting water ran off, and the ice lying upon the western part of the crater and the inner walls issued in the form of a glacier. What a wonderful contrast between this icy stream and the former fiery incandescence of its bed! And above all this there reigned the absolute silence of inanimate nature, forming in its majestic simplicity a scene of the most impressive grandeur. An indelible impression was created in the mind of the traveller to whom it had once been granted to gaze upon a scene like that, and all the more when no human eye had previously beheld it. And certainly as they sat that evening in their little tent, which they finally reached at nightfall, after a most arduous return march through the driving mist, and carried their thoughts back to the expeditions of 1887

and 1888, they would indeed have changed places with no one. After giving further details of the expedition, the lecturer said that on October 30 they sorrowfully bade farewell to Kilima-Njaro, the most beautiful and interesting, as well as the grandest, region in the dark continent. At the conclusion of the paper a series of photographs illustrative of some features of the expedition was exhibited by lime-light, and explained by Mr. Ravenstein. A vote of thanks to Dr. Meyer was proposed by Mr. Joseph Thomson, seconded by Mr. Douglas Freshfield, and heartily accorded.

A NEW GREEN VEGETABLE COLOURING MATTER.[1]

THE seeds of the *Trichosanthes palmata* are inclosed in a rounded scarlet fruit and embedded in a green bitter pulp. The bitter principle has been shown by Mr. D. Hooper to be a glucoside differing from colocynthin, and he has named it trichosanthin. The green colouring matter, when freed from the trichosanthin and fatty matter, yields a solution closely resembling a solution of cholorophyll. It is green in thin and red in thick layers, and has a red fluorescence. The spectrum, however, is very different. Taking the thickness and strength yielding the most characteristic spectrum, it may be described thus:—The first band begins (penumbra) at W.L. 654 and ends about W.L. 615; from this there is a small amount of absorption till the second band begins at W.L. 593·4, and continues to W.L. 566·8, with the maximum absorption near the less refrangible end; from this there is no perceptible absorption till the third band, which extends from W.L. 548·4 to 534·8; there is a fourth band, very faint, with its centre about W.L. 510·6, and a fifth extending from about W.L. 485 to W.L. 473·4. Comparing this with the chlorophyll spectrum, it will be seen that the first band has its centre almost midway between the two chief chlorophyll bands, but that bands III., IV., and V. are probably coincident with chlorophyll bands. When the trichosanthes colouring matter is treated with ammonia sulphide the spectrum is completely changed. The first and most prominent band slowly decreases in strength and finally disappears, two new bands appear in the space between bands I. and II. of the original spectrum; band II. is apparently displaced towards the violet end and intensified; and band IV. is greatly widened. Chlorophyll under the same treatment behaves in a totally different manner, and the two spectra become almost complementary. When, however, the trichosanthes colouring matter and chlorophyll are both treated with hydrochloric acid the result is very different, for the two spectra have now three bands in common. The first band in the trichosanthes spectrum has disappeared, and the spectrum is practically reduced to one of three bands corresponding in position with bands II., III., and IV. of the altered chlorophyll spectrum. Band I. of the chlorophyll spectrum has no representative in the trichosanthes spectrum. The conclusions to be derived from a study of these spectra seem to be that we have in the trichosanthes colouring matter a substance in which the "blue chlorophyll" of Sorby or the "green chlorophyll" of Stokes is replaced by some other substance easily decomposed by reducing agents and acids. Farther, if we assume with Schunck that the product obtained by acting on chlorophyll with hydrochloric acid is the same as Frémy's phyllocyanin, this, too, must be a mixture, one constituent of which is obtained by acting on the trichosanthes colouring matter with acid, while the other is, apparently, the unaltered substance yielding band I. in the chlorophyll spectrum.

SOCIETIES AND ACADEMIES

LONDON.

Royal Society, March 13.—"On the Organization of the Fossil Plants of the Coal-measures. Part XVII." By William Crawford Williamson, LL.D., F.R.S., Professor of Botany in the Owens College, Manchester.

In 1873 the author described in the Phil. Trans. an interesting stem of a plant from the Lower Carboniferous beds of Lancashire, under the name of *Lyginodendron Oldhamium*. He also called attention to some petioles of ferns, more fully described in 1874, under the name of *Rachiopteris aspera*. The former of these plants possessed a highly organized, exogenously developed xylem zone, whilst the *Rachiopteris* was only supplied with what looked like closed bundles. Since the dates referred to, a large amount of additional information has been obtained respecting both these plants. Structures, either not seen, or at least ill-preserved, have now been discovered, throwing fresh light on their affinities; but most important of all is the proof that the *Rachiopteris aspera* is now completely identified as the foliar rachis or petiole of the *Lyginodendron*: hence there is no longer room for doubting that, notwithstanding its indisputable possession of an exogenous vascular zone, the bundles of which exhibit both xylem and phloëm elements along with medullary and phloëm rays, it has been a true Fern. Though such exogenous developments have now been long known to exist amongst the Calamitean and Lycopodiaceous stems, as well as in other plants of the Carboniferous strata, we have had no evidence until now that the same mode of growth ever occurred amongst the Ferns. Now, however, this Cryptogamic family is shown to be no longer an exceptional one in this respect. All the three great divisions of the Vascular Cryptogams—the Equisetaceæ, the Lycopodiaceæ, and the Homosporous Filices of the primæval world—exhibited the mode of growth which is confined, at the present day, to the Angiospermous plants. A further interesting feature of the life of this *Lyginodendron* is seen in the history of the development of its conspicuous medulla. In several of his previous memoirs, notably in his Part IV., the author has demonstrated a peculiarity in the origin of the medulla of the Sigillarian and Lepidodendroid plants. Instead of being a conspicuous structure in the youngest state of the stems and branches of these plants, as it is in the recent Ferns, and as in most of the living Angiosperms, few or no traces of it are observable in these fossil Lycopodiaceæ. In them it develops itself in the interior of an apparently solid bundle of tracheæ (within which doubtless some obscure cellular germs must be hidden), but ultimately it becomes a large and conspicuous organ. The author has now ascertained that a similar medulla is developed, in precisely the same way, within a large vascular bundle occupying the centre of the very young twigs of the *Lyginodendron*. But in this latter plant other phenomena associated with this development make its history even yet more clear and indisputable than in the case of the Lycopods. The entire history of these anomalous developments adds a new chapter to our records of the physiology of the vegetable kingdom.

Further light is also thrown upon the structure of the *Heterangium Grievii*, originally described in the author's memoir, Part IV. This plant presents many features in its structure suggesting that it too will ultimately prove to be a Fern. The specimens described in the above memoir, published in 1873, all possessed a more or less developed exogenous xylem zone. But the author has now obtained other, apparently younger examples in which no such zone exists.

He has discovered the stem of a genus of plants (*Bowmanites*), hitherto known only by some fruits, the detailed organization of which was originally described by him in the Transactions of the Literary and Philosophical Society of Manchester, in 1871. The structure of this new stem corresponds closely with what is seen in *Sphenophyllum* and in some forms of *Asterophyllites* (Memoir V., Phil. Trans., 1874, p. 41, *et seq.*). This discovery makes an addition to our knowledge of the great Calamarian family, to which the plant obviously belongs.

Further demonstrations are also given by the author, illustrating some features in the history of the true Calamites. Attention is called to the fact that, whilst the large, longitudinally-grooved and furrowed inorganic casts of the central medullary cavities of these plants are extremely common, we never find similar casts of the smaller branches. The cause of this is demonstrated in the memoir. In these young twigs the centre of the branch is at first occupied by a parenchymatous medulla. The centre of this medulla becomes absorbed at a very early age, leaving the beginnings of a small fistular cavity in its place; but, if any plastic mud or sand entered this cavity when the plant was submerged, the surface of such a cast would exhibit no longitudinal groovings, because there would be nothing in the remaining medullary cells surrounding the cast to produce such an effect. It was only when the further growth of the branch was accompanied by a more complete absorption of the remaining medullary cells, causing the cavity thus produced to

[1] Abstracted from a paper by C. Michie Smith, "On the Absorption Spectra of Certain Vegetable Colouring Matters," read before the Royal Society of Edinburgh, March 17, 1890, and communicated by permission of the Council.

be bounded by the inner wedge-shaped angles of the longitudinal vascular bundles constituting the xylem zone, that such an effect could be produced. After that change any inorganic substance finding its way into the interior of this cavity had its surface so moulded by the wedges as to produce the superficial ridges and furrows so characteristic of these inorganic casts.

March 27.—"The Rupture of Steel by Longitudinal Stress." By Chas. A. Carus-Wilson. Communicated by Prof. G. H. Darwin, F.R.S.

This paper gives an account of experiments made with a view to determining the nature of the resistance that has to be overcome in order to produce rupture in a steel bar by longitudinal stress.

The stress required to produce rupture is in every case computed by dividing the load on the specimen at the moment of breaking by the contracted area at the fracture measured after rupture; this stress is called the "true tensile strength" of the material.

It is well known that any want of uniformity in the distribution of the stress over the ruptured section causes the bar to break at a lower stress than it would if the stress was uniformly distributed. Hence anything that causes want of uniformity is prejudicial; for instance, a groove turned in a cylindrical steel bar will produce want of uniformity, and will consequently be prejudicial, the stress at rupture being lower according as the angle of the groove is more acute. The most favourable condition of test might appear to be that in which a bar of uniform section throughout its length was allowed to draw out freely before breaking, since in this case the stress must be most uniformly distributed.

Experiment, however, shows that the plain bar is not always the strongest. So long as the want of uniformity of stress is considerable, owing to the groove being cut with a very sharp angle, the plain bar is stronger than the grooved bar; but, if the groove be semicircular instead of angular, the grooved bar is considerably stronger than the plain, in spite of the fact that the stress is more uniformly distributed in the latter.

It would seem, then, that we can strengthen a bar over any given section by adding material above and below it, the change in section being gradual; but such an addition of material cannot strengthen the bar if rupture is caused by a certain intensity of tensile stress over the ruptured section; the added material cannot increase the resistance of the ruptured section to direct tensile stress, but it can increase the resistance to the shearing stress.

The resistance of a given section of a steel bar does not, then, depend on its section at right angles to the axis, but on its section at 45° to the axis, for in that direction the shearing stress is a maximum. From this it would seem that the resistance overcome at rupture is the resistance of the steel to shear.

Experiments were made to see whether the resistance of steel to direct shearing bore to its resistance to direct tension the ratio required by the above theory; since the greatest shearing stress is equal to one-half the longitudinal stress, we should expect to find the resistance to direct shearing equal to one half of the resistance to direct tension.

A series of experiments were made, with the result that the ultimate resistance to direct shearing was within, on the average, 3 per cent. of the half of that to direct tension.

The appearance of the fracture of steel bars is next discussed. It would appear that when the stress is uniformly disturbed in the neighbourhood of the ruptured section, the fracture is at 45° to the axis, the bar having sheared along that plane which is a plane of least resistance to shear. The tendency to rupture along a plane of shear may be masked by a non-uniform distribution of stress.

Two plates of photographs are added, showing examples of steel bars broken by shearing under longitudinal stress.

Physical Society, March 21.—Prof. W. E. Aryton, F.R.S., President, in the chair.—The following communications were read:—The Villari critical points in nickel and iron, by Herbert Tomlinson, F.R.S. Villari has shown that the permeability of iron is increased by longitudinal traction provided the magnetizing force does not exceed a certain limit, but beyond this limit traction produces a decrease of permeability. The value of the force for which traction produces no change in the permeability is known as the Villari critical point. As far as the author is aware, no previous observer has found a similar critical point for nickel, but by confining his attention to *temporary* magnetization he has detected such a point with comparative ease. He has also examined the variation of the Villari critical points in iron and nickel with change of load, and has investigated the influence of permanent strain on these points. The experiments were made by the ballistic method, using wires about 400 diameters long. In each set of observations the permeability was obtained with various loads, the magnetizing force being kept the same, and with each load the circuit was closed and opened until the swings on make and break were equal; this swing was taken as a measure of the induction under the given load. Several diagrams accompany the paper, in which load and percentage change of permeability are plotted, regard being had to sign. The author finds that for annealed unstrained iron the critical value of the force decreases as the load increases, and that the Villari point is much lower for *temporary* than for *total* magnetization. With a load of 4·7 kilos on a 1 mm. wire, the value of the force giving the temporary point was 2·8 C.G.S. units. He also found that for a given magnetizing force there are generally two loads which have no effect on the temporary magnetization. With unstrained nickel the critical value of the force is much greater than in iron, being about 114 C.G.S. units for a load of 10 kilos on a wire 0·8 mm. diameter, and 67 for a load of 6·6 kilos. For a force of 21 units no critical point exists. Experiments on a permanently strained iron wire show that for magnetizing forces ranging from 0·03 to 0·3 there is no critical point, and all the resulting curves are identical. There is, however, considerable difference in the observations taken during loading and those taken on unloading. For greater magnetizing forces the curves cease to be identical, and the maximum increase of permeability becomes less and less until for a certain force the curves begin to cut the load line. As the force increases beyond this value the point of cutting approaches the origin, and the curves begin to cut the load line in two points. Further increase of force to 3 C.G.S. units causes the first point to disappear, and the second point recedes from the origin. Finally, with sufficiently high magnetizing forces the second point cannot be reached before the wire breaks, and the curve lies entirely below the load line. With nickel the curves for very minute forces, like those of iron, are exactly the same for different values of the force, but they lie below the load line, *i.e.* the permeability is diminished by loading; there is no difference, however, in the loading and unloading curves. Beyond a certain value of the force the identity of the curves ceases, and that part of the curve near the origin bulges towards the load line. For a force a little over 21 C.G.S. units the permeability begins to increase with load, and the curve cuts the line in one point, which point recedes from the origin as the force increases. Mr. Shelford Bidwell said that Prof. J. J. Thomson, reasoning from the change of length by magnetization, had predicted a Villari point in cobalt when compressed, and this was verified experimentally. On applying similar reasoning to nickel he, (the speaker) did not expect to find a Villari point, and both Sir William Thomson and Prof. Ewing had searched in vain for one. In some experiments, not yet completed, he had examined the behaviour of nickel, both loaded and unloaded, when subjected to various magnetizing forces. These show that the metal always contracts when magnetized. For no load the contraction at first increased with the magnetizing force, but attains a maximum. With a moderate load the contraction is less for small forces, but for larger forces becomes equal and then exceeds the contraction of the unloaded wire. For greater loads the contraction is less than when unloaded for all values of the force.—On Bertrand's Idiocyclophanous prism by Prof. S. P. Thompson. This hitherto undescribed prism is a total reflection one made of calc-spar, which shows to the naked eye the rings and crosses such as are seen when a slice of spar is examined by convergent light in a polariscope. The spar is cut so that the light after the first reflection passes along the optic axis, and after a second reflection emerges parallel to the incident light. The rings and brushes are present in pairs, but two pairs may be seen by tilting the prism to one side or the other. This was demonstrated before the Society. Prof. Thompson also exhibited a similar prism cut from quartz. Owing to the feeble double-refracting of the substance, no conspicuous rings could be seen, but when examined by the lantern traces of such rings were visible.—On the shape of the movable coils used in electrical measuring instruments, by Mr. T. Mather. The object of this note is to determine the best shape of the horizontal section of swinging coils such as are used in D'Arsonval galvanometers,

electro-dynamometers, wattmeters, &c. Assuming constant period and constant moment of inertia about the axis of rotation, it is shown that for zero instruments, the best shape of the section is two circles tangential to the direction of the deflecting field at the point about which the coil turns. A table accompanies the paper, in which various forms of section are given, together with their relative deflecting moments per unit moment of inertia; the coils being taken of equal lengths and the current density constant. From this table it appears that ordinary D'Arsonval coils only give about 45 per cent. of the maximum deflecting moment, and ordinary Siemens' dynamometers from 40 to 53 per cent. The various assumptions made in the paper are shown to be justifiable in commercial instruments, and the modifications necessary in special cases are pointed out. Mr. C. V. Boys said he had, when working at his radio-micrometer, arrived at a shape similar to that recommended in the paper. He also noticed a peculiar relation true for all shapes where the length parallel to the axis of rotation is great compared with the breadth. Suppose a coil of any dimensions, then another coil of half the breadth and double the length and cross-section will be dynamically, electrically, and magnetically the same as the original; for the moment of inertia, the electric resistance, and the enclosed magnetic field are equal. The above relation is also true when the breadth is not small, if the cross pieces be thickened near the axis so as to make their moment of inertia proportional to their length. He inquired whether the author had considered the subject of grading movable coils; he himself was of opinion that, unlike fixed galvanometer coils, the wire near the axis should be thicker than that further away. The President remarked that in 1881 Prof. Perry and himself exhibited a wattmeter at the Society of Arts, whose movable coil somewhat resembled one of those in the paper, which gave a deflecting moment of 95 per cent. of the maximum. In designing the instrument they had felt that the ordinary method of using a comparatively large swinging coil was not the best, and this led them to the shape adopted.

Entomological Society, April 2.—Mr. Frederick DuCane Godman, F.R.S., Vice-President, in the chair.—Mr. Godman announced the death of Dr. J. S. Baly, of Warwick, the well-known Coleopterist, who had been a member of the Society for the last forty years.—Dr. Sharp exhibited and made remarks on a female specimen of *Temnochila quadricollis*, Reitt., which was the subject of a very unusual malformation of the nature termed "ectromélie" by Lacordaire.—Mr. R. W. Lloyd exhibited three specimens of *Elater pomonæ*, taken at Brockenhurst about the middle of March last.—Colonel Swinhoe exhibited, and read notes on, a number of butterflies of the genus *Euthalia*. He pointed out that the specimens described as a species by the name of *Euthalia sedeva* were only the females of *E. balarama*.—Mr. T. R. Billups exhibited male and female specimens of *Cecidomyia salicis-siliqua*, Walsh, which had just emerged from galls received from Mr. Cockerell, who had collected them on a species of sallow in Colorado. He also exhibited three species of Ichneumonidæ new to Britain, viz. *Ichneumon haglundi*, Holmgr.; *Phygadeuon rufo-niger*, Bridg.; and *Phygadeuon sodalis*, Tasch.—Mr. C. G. Barrett exhibited specimens of *Bryotropha obscurella*, Hein, and *Doryphora elongella*, Hein, two species of Micro-Lepidoptera new to Britain.—Dr. Thallwitz, of Dresden, contributed a paper entitled "Notes on some species of the genus *Hilipus*." These notes had reference to a paper on the genus *Hilipus*, by Mr. F. P. Pascoe, published in the Transactions of the Society for 1889.—Mr. E. Meyrick read a paper entitled "The Classification of the Pyralidina of the European Fauna."—Prof. Westwood communicated a paper entitled "Notes on certain species of Cetoniidæ."—Mynheer P. C. T. Snellen, of Rotterdam, contributed a paper entitled "A Catalogue of the Pyralidæ of Sikkim collected by H. J. Elwes and the late Otto Möller," and Captain Elwes read notes on the foregoing paper as an appendix. Mr. W. L. Distant, Colonel Swinhoe, Mr. McLachlan, and Mr. Jacoby took part in the discussion which ensued.

Zoological Society, April 1.—Dr. A. Günther, F.R.S., Vice-President, in the chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the month of March 1890; and called special attention to a fine example of a rare Passerine Bird (*Hypocolius amplinus*) from Karachi, presented to the Society by Mr. W. D. Cumming, Curator of the Museum, Karachi; and to two Mantchurian Cranes (*Grus viridirostris*), presented to the Society by Mr. C. W. Campbell, of H.B.M.'s Consular Service, Corea.—Mr. J. H. Gurney, Jun., exhibited and made remarks on a hybrid between the Tree-Sparrow (*Passer montanus*) and the House-Sparrow (*P. domesticus*), bred in captivity at Norwich.—Mr. W. B. Tegetmeier, exhibited a specimen of a Greek Partridge, shot in the Rhone Valley, and of an abnormal Viper.—Mr. A. Smith-Woodward exhibited and made remarks on a specimen of a Mesozoic Palæoniscid Fish from New South Wales, and pointed out that the structure of its pelvic fins seemed to confirm the recent opinion that the Palæoniscidæ are related to the Acipenseridæ and not to the Lepidosteidæ. The author believed the specimen exhibited to be the only one of the kind in existence.—Mr. C. M. Woodford made some remarks on the fauna of the Solomon Islands; and exhibited a large number of photographs in illustration of his remarks and of his recent explorations in these islands.—A communication was read from Dr. R. W. Shufeldt, entitled "Contributions to the Study of *Heloderma suspectum*," containing a complete account of the osteology and anatomy of this venomous Lizard. A list of the literature on the subject was added.—Dr. A. Günther, F.R.S., read the descriptions of new species of Deep-sea Fish from the Cape (*Lophotes fiski*), based on a specimen sent to the British Museum by the Rev. G. H. R. Fisk.—Mr. Edgar A. Smith, read a report on the Marine Molluscan Fauna of the Island of St. Helena, based principally on a large series of specimens collected by Captain Turton, R.E., and presented to the British Museum.—A second paper by Mr. Edgar A. Smith contained a report on the Marine Mollusca of Ascension Island.

Mathematical Society, April 3.—J. J. Walker, F.R.S., President, in the chair.—The following communications were made:—On the properties of some circles connected with a triangle formed by circular arcs, by Mr. Lachlan.—Some properties of numbers, by Mr. Christie.—The modular equations for $n = 17, 29$, by Mr. R. Russell. Communicated by Prof. Greenhill, F.R.S.

EDINBURGH.

Royal Society, March 17.—Sir W. Thomson, President, in the chair.—The President read a paper on an accidental illustration of the effective ohmic resistance to a transient electric current through an iron bar.—Prof. C. Michie Smith read a paper on the absorption spectra of certain vegetable colouring matters, the most interesting of which was a green colouring matter extracted from the pulp surrounding the seeds *tricosanthes palmata*. This substance is not chlorophyll, but is allied to it.—Prof. Smith also described a method of determining surface tensions by measurement of ripples. Ripples are set up on the surface of the liquid by means of a tuning-fork and the surface is then photographed along with a suitable scale. The lengths of the ripples can thus be obtained by micrometric measurements of the negative. The results obtained for mercury were very concordant, and agreed with the mean value obtained by Quincke. Strong electrification of the surface was found to reduce the value of the surface tension by more than 20 per cent. A few measurements of the surface tension of water also gave very fair results.—The Hon. Lord M'Laren read a paper on the solution of the three-term numerical equation of the nth degree.—The President read a paper, illustrated by a model, on a mechanism for the constitution of ether.

PARIS.

Academy of Sciences, April 8.—M. Duchartre in the chair.—M. Maurice Lévy, in a note on theories of electricity, shows that the formula given in his communication on March 17, representing the action between two moving electric particles, includes all the theories of electricity yet proposed, and that the values of an arbitrary constant required to satisfy each of the known theories are none of them competent to explain the movement of the perihelion of Mercury, whereas the latter is completely in accordance with the formula when another suitable value is chosen for the constant.—M. R. Lépine, in a note on the normal presence in chyle of a ferment destroying sugar, suggests that in the majority of cases of diabetes the disease is probably due to a defect in the production of this necessary body.—Observations of Brooks's comet (a 1890), made with the great equatorial of Bordeaux Observatory, by MM. Rayet, Picart, and Courty. The comet was observed on March 30 and 31, and

April 2 and 3.—Elements and ephemeris of Brooks's comet, by M. E. Viennet. Elements have been computed from observations at Cambridge, U.S., March 21; Kremsmunster, March 26; and Paris, March 31.—Observations of Brooks's comet, made at Paris Observatory, by Mdlle. D. Klumpke.—Fundamental common property of the two kinds of spectra, lines and bands; distinct characteristics of each of the classes; periodic variations to three parameters, by M. H. Deslandres. The facts relating to the periodic recurrence of doubles and triplets in spectra were previously given by M. Rydberg, and reduced to some simple laws (*Comptes rendus*, February 24). It was noted that the lines corresponding to doubles and triplets are represented by a function of whole numbers of the form $N = A - \frac{\alpha}{(m+p)^2}$; where N is the number of waves; A, α, two constants; p a constant less than one, and m a whole number. This function has for a limit the more simple one $N = A - \frac{\alpha}{m^2}$, which, when A and α have proper values, represents exactly, as was shown by Balmer, the unique series of the simple lines of hydrogen. The author states that the distribution of bands is in general more complex, the complete series of groups being represented by a function of three variable parameters, m, n, p—$N = f(n^2p^2) \times m^2 + Bn^2 + \phi(p^2)$; where m, n, and p, are whole numbers; B, a constant; f and ϕ some simple functions the study of which is not completed. N is a function of three parameters, but in certain spectra it is reduced to two or even one. This distribution depending on three parameters is a distinct characteristic of a band spectrum.—On the suppression of halos in photographic plates, by MM. Paul and Prosper Henry. *A propos* of a communication by M. Cornu (*Comptes rendus*, March 17), the authors note that in order to get rid of halos which occur around bright stars on an ordinary photographic plate they cover the backs of plates with collodion containing a small quantity of chrysoidine in solution.—Discharge of the two electricities by the action of ultra-violet light, by M. Edouard Branly. The author has obtained new results by using the induction spark as his source of light in place of the electric arc used by previous observers.—On phosphotrimetatungstic acid and its derived salts, note by M. E. Péchard.—On a nitrosoplatinichloride, by M. M. Vèzes. By the action of an excess of hydrochloric acid on a concentrated solution of potassium platinonitrite, a body is obtained of the composition $PtCl_3(NO),2KCl$, analogous to but much less stable than the nitrosoruthenichloride, $RuCl_3(NO),2KCl$, described by M. Joly (*Comptes rendus*, t. cvii. p. 994). It is distinguished from the platinichloride under the microscope by its form and by its action on polarized light.—Glycollic nitrile and the direct synthesis of glycollic acid, by M. Louis Henry. The nitrile is formed by the addition of formic aldehyde to hydrocyanic acid, $HCOH + HCN = CN—CH_2OH$. The glycollic nitrile obtained is a very mobile, odourless, colourless liquid; its density at 12° is 1·100, it boils at 759 mm. pressure at 183° with partial decomposition. By hydrolysis with fuming hydrochloric acid, it yields glycollic acid, which may be separated as the calcium salt. This, in the opinion of the author, is the best method for the preparation of glycollic acid.

STOCKHOLM.

Royal Academy of Sciences, March 13.—On the International Zoological Congress in Paris in 1889, by Prof. F. A. Smitt.—A continuation of the Report of the Ornithological Committee, by Prof. F. A. Smitt.—On the results of the recent winter expedition for hydrographic researches in Skager Rack, by Prof. S. O. Pettersson.—Analytical deduction of the equations of the surfaces and lines which are invariants to the generalized substitution of Poincaré, and some geometrical properties of such invariant surfaces and lines, by F. de Brun.—On a special class of singular surfaces, by T. Fredholm.—On the solution of a system of linear resemblances between an infinite number of unknown quantities, by H. von Koch.—On a paper by H. Weber, entitled "Ein Beitrag zu Poincaré's Theorie der Fuchs'schen Functionen," by G. Cassel.—On the conform representation of a plane on a prism with some correlated problems, by the same.—Researches on mustard-oil-acetic acid and on thiohydantoin, by Prof. Klason.—Derivates of 1 : 3 dichlornaphthalin, by Prof. Cleve.—On the cyclic system of Ribaucour, by Prof. Bäcklund.—Contribution to the knowledge of the Ascomycetæ of Sweden, by C. Starbäck.—Determination of the optical rotation of some resinous derivates, by A. W. Svensson.—Studies on the influence of the irritation of the spinal chord and the nervus splanchnicus on the pressure of the blood with inductions of different frequency and intensity, by J. E. Johansson.

THURSDAY, APRIL 24, 1890.

THE REVISED INSTRUCTIONS TO INSPECTORS.

LAST year it was a matter of considerable complaint against the Education Department that the Draft Code was presented to Parliament unaccompanied by the new instructions to inspectors, without which it could neither be satisfactorily interpreted nor adequately discussed. No such complaint can be made this year. The issue of the new Code, which promises to place elementary schools under what is practically a new system of regulations, has been followed within a few days by a revised edition of the instructions to inspectors, in which the changes are correspondingly large. Indeed, more than half of the document consists of new matter.

On the whole, the approbation which has greeted Mr. Kekewich's Code may be extended to the instructions by which it is explained. So far as we can see, there is no shuffling, no attempt to minimise or to alter the practical effect of the reforms which are conceded on paper in the Code.

The main alterations occur in those parts of the instructions which are to guide the inspector in awarding the Parliamentary grant under the new *régime*. It will be remembered that the system of payment on the results of individual examination disappears almost completely, and is replaced by a grant made up of three parts—a "principal grant" of 12*s.* 6*d.* or 14*s.*, a grant of 1*s.* 6*d.* or 2*s.* for discipline and organization, and a payment as before on results of examination in the so-called "additional subjects." The mode of examination to be adopted in future in the elementary subjects on which the "principal grant" depends is substantially that already in use for "class subjects." That is to say, there will be a collective examination by sample, a certain proportion of children out of each class being chosen at random for examination by the inspector, the teacher being always invited to add a few of his most forward scholars, so that the school may not be injured by any accident in the selection. Several alternative modes of selection are suggested, and the inspector is expressly asked to vary his method from time to time, rather than to adopt any uniform plan. Teachers and managers may hear the oral examination and see the papers, but they are to be warned that "it is not by studying past questions, nor by trying to forecast the kind of questions likely to be set hereafter, but by teaching the subject with good sense and thoroughness that the requirements of the Department will be best fulfilled, and the truest educational success achieved."

The higher "principal grant" is not to be awarded unless a high standard of proficiency is reached in all three elementary subjects. If the scholars do not reach the standard required for the lower "principal grant," the managers are to be warned that next year the grant may be discontinued; and, in all cases where the higher grant is not awarded, the points in which the school is deficient are to be clearly indicated to the managers.

These regulations, if wisely carried out, must be a great improvement on those under which the grant is at present assessed. The old barbarous system of bleeding a bad school to death by diminishing its grant below the minimum required for its efficient maintenance will be discontinued. In place of this a school, so long as it receives anything, will receive enough to enable it to be efficient if the teachers and managers are up to their work. If such a school fails to reach the required standard, though supplied with public aid on as liberal a scale as that on which multitudes of schools do contrive to be efficient, it will simply be removed from the list of grant-earning schools. This is the rational course, if carried out in practice, but very much will depend on the inspector. It is sincerely to be hoped that the instructions will be carried out in such a way as to ensure that the "liberal grant now offered to comparatively humble schools shall serve as an aid and stimulus to improvement, and not as a pretext for remaining content with a low standard of duty."

With the disappearance of payment on individual results in the elementary subjects, the necessity for many of the minute regulations as to the exact meaning of a "pass" in each subject disappears also. But the necessity still remains for the inspector to keep in mind the standard of an individual pass for such purposes as that of the scholar requiring a "labour pass" either for half-time or whole-time exemption.

A few modifications are made in the instructions respecting the three elementary subjects. The justice of the oft-repeated complaints which have been made of the excessive time devoted to English grammar is recognized, not only in the altered regulations for English, but in a great reduction in the "spelling" requirements. As regards reading, it is suggested that a class of older scholars should be set to read a passage to themselves while another class is being examined, and then be questioned as to its matter. Writing will be partly tested by examination of school copy-books, not merely by a piece of writing executed during the anxious and nervous hours of the inspector's visit.

But the most important changes bearing on the school curriculum—indeed, perhaps, on the whole, the most important changes in the whole document—are those passages in which an attempt is made to link the instruction of the school to the life of the home. On the one hand, the co-operation of the parents is to be expressly invited; on the other hand, their special wants are to be more directly consulted. For example, it is pointed out that "in some good schools the aid of the parents has been successfully enlisted, and they have been urged to hear their children read aloud from a newspaper or from a book for a few minutes at home in every day. The amount of oral practice which any one child can obtain in a large class is obviously insufficient; and a little home exercise in reading aloud is often found to have an excellent effect." On the other hand, the elder girls are to be allowed to bring from home garments that want mending, and to repair them in school under the teachers' supervision—an arrangement which will "connect the school-work usefully with the every-day life of the scholars." There are other hints to a similar effect, as in the concluding paragraphs of the instructions, which enumerate the ways in which, besides conforming to the requirements of the Code, a school may seek "to render

service to the children who attend it and to their parents." Taken one by one, the suggestions may seem unimportant; collectively, however, they indicate a policy of taking the parents frankly into confidence, and so, if possible, of establishing a new link of interest between the parent and the school, besides the mere "cash-nexus" of the school pence, which are destined so soon to disappear.

Under the head of "class subjects" an explanation is given of the object of the great changes in Schedule II., which, we learn, have been introduced in order to allow of greater freedom to teachers of different tastes and capacities, and to localities of different industries and requirements. "One good teacher of geography may attach special value to physical facts and phenomena; another who lives in a manufacturing or maritime town prefers to make commercial and industrial geography and the interchange of productions the leading features of his lessons." The same standard is, so far as possible, to be kept in view, in estimating the teaching of all the various alternative courses; but, subject to this one consideration, complete freedom of choice and treatment is to be given to teachers and managers. "In sanctioning any modification of the printed schemes it will be necessary to have regard to the experience and qualifications of the teacher, and to any special opportunities afforded in the town or district for instruction by a skilled demonstrator, who visits several schools in succession, or who gives collective lessons at suitable centres."

The instructions further confirm the view we expressed when commenting on the Code, that the policy of the Department will be to encourage class teaching at the expense of specific subjects. "Those managers and teachers who desire to continue the object-lessons of the infant school in due order through all the lower standards, and so to lead up to the regular study of natural history or physics in the higher, will probably think it better to treat science as a class subject than to postpone specific instruction until the fifth standard."

The recognition of continuity, and the idea of the school course as a connected whole, strikes us as a new and valuable feature in the instructions. From the infant school the child is to be led on through a series of object-lessons to the scientific class-teaching of the upper school, and thence in some cases to specific instruction in the higher standards. But all this is but the beginning. "Teachers should not be satisfied unless the instruction in specific subjects awakens in the scholar a desire for further knowledge, and makes him willing to avail himself of such opportunities as are afforded locally by a Science Class, a Polytechnic Institute, a course of University Extension Lectures, a Free Library, or a Home-Reading Circle." All this is a truism, it may be said; but it is unusual language for an official document, and carries us forward in imagination to the time, which must come sooner or later, when such fragmentary and scattered institutions as are here enumerated will take their proper place as parts of a great scheme of national education.

We fear that the realization of the aims of the Department may be materially impeded if a literal construction is to be placed on the clause providing that the same subject may not be taken both as a "class" and as a "specific" subject. Does this restriction merely mean that no child is to be presented in the same subject under both heads—an obviously reasonable stipulation—or that no children in a school may take as a specific subject any branch of study which is taken as a class subject by any other children in the school? If the latter is the case, we are informed that, in some cases at least, managers will find themselves seriously hampered.

Provision is made for the assistance of experts in the examination of scholars, in cases where the managers choose an "additional" subject with which neither the inspector nor his assistants are fully conversant. But unfortunately this assistance, which will be given by a colleague, on application to the chief inspector, will be confined to the framing of suitable questions, and marking the answers, and hence will be inapplicable to the case of oral examination, in which it is most wanted.

Those interested in manual instruction will turn with interest to the thirty-fifth section, which lays down the duties of inspectors with respect to this newly recognized branch of instruction. It explains that the difficulty which has hitherto prevented the recognition of manual instruction as part of the ordinary course of instruction in a public elementary school has been removed by the alteration in the terms of Art. 12 (*f*), though how such a change in Departmental regulations can alter the sense of an Act of Parliament we are left to conjecture. The instructions suggest such exercises as "modelling, the cutting, fixing, and inventing of paper patterns, the forming of geometrical solids in cardboard, and the use of tools and instruments," which are in use in some foreign schools, and are found to be "not without a useful reflex influence on all the ordinary school studies." The inspector is to report on the working of any system of manual instruction which may be adopted, though "no special grant is made *by this Department*." The words we have italicized clearly tend to confirm our impression as to the intention of the Science and Art Department to include manual instruction in their next Directory.

It is rather strange that under the head of "drawing" no reference is made to the change by which in future drawing will be made compulsory in boys' schools and optional in infant departments. It is true that drawing in ordinary schools will, as now, be paid for by the Science and Art Department, but power is given by the new Code to Her Majesty's Inspector to exempt schools from the necessity of taking the subject where the means of teaching it cannot be procured. We should like to know what standard the inspector will adopt in using this dispensing power. Will the standard be the same in all districts?

This is the question to which we return again and again after examining in detail the various changes in the Code and the instructions. All will depend on the inspectors. What will their action be? We agree on the whole in the praise accorded in the instructions to the "ability, discretion, and fairness with which Her Majesty's Inspectors discharge their arduous duties," but nevertheless, in particular cases, complaints of their action have not been wanting. The inspectors have hitherto been burdened with an amount of routine work which has to some extent hindered them from forming a really intelligent estimate of the value of the school work which they have to assess. This burden is now lightened, more visits may be paid without notice, and thus more intimate knowledge may be acquired of the real work of the school. "It will be

largely owing," we read, "to your influence if all who are concerned with the management of schools habitually regard the officers of this Department not merely as critics and examiners, but as advisers and helpers, in the performance of an important public work." That is the ideal to aim at, though there is a good deal of lee-way to make up before it is realized.

ORANGES IN INDIA.

The Cultivated Oranges and Lemons of India and Ceylon. By E. Bonavia, M.D. Pp. 384, with an Atlas of 259 Plates 7 inches long by 9 inches broad. (London: W. H. Allen, 1890.)

FOR twenty years past Dr. Bonavia has been distinguished in India as a horticulturist. He has been in charge of the Horticultural Gardens at Lucknow, where he has conducted many valuable experiments. Of late years he has tried oranges, and he has also collected information concerning oranges from various parts of India. India, taken as a whole, is very poorly supplied with fruit; really good mangoes and litchis are nearly everywhere dear, and remain in season but a short time. Oranges in several parts of India are cheap and excellent; improvement in their cultivation and extension in their circulation are matters of importance. The book of Dr. Bonavia contains his own experiences and notes, which are valuable. His second-hand information, which he has collected in the fashion of an Indian Secretary to Government or Minister of Agriculture, is of very small value, but is certainly superior to many secretarial compilations about hemp, jute, cotton, &c.

The first ninety pages treat of the various groups of oranges, lemons, limes, citrons, &c., with their sub-varieties; the next fifty pages treat of their cultivation in India; fifteen pages treat of their uses; eleven of the orange trade in India; twenty-one of the morphology of Citrus; forty of the origin of the Citrus and the derivation of its Indian names. Then follow 120 pages of appendix, containing a miscellaneous collection of "cuttings" relating in some way to the subjects in the book, with a translation of the chapters relating to Citrus in Rumphius's "Herbarium Amboinense." The greater part of this appendix appears of small importance; while Dr. Bonavia has by no means exhausted what first-rate authorities have written regarding oranges. The atlas of plates gives hardly anything but outline drawings of oranges and their leaves; a very small selection of these would have served every useful purpose.

Dr. Bonavia has summed up for us the conclusions of his book under seven heads (p. 245):—

(*a*) The pummelo (*Citrus decumana*, Willd.), is not specifically separable from the orange (*C. Aurantium*, Linn.).—This is a point of no possible importance, when naturalists know no line between a well-marked variety and a dubious "species"; but Lowe ("Fl. Madeira," p. 73) agrees with Dr. Bonavia.

(*b*) The sweet orange of Europe (*C. Aurantium*, Linn.) is a distinct race from the Mandarin orange (*C. nobilis*, Lour.).—This is correct, and well brought out by Dr. Bonavia; but it is also done very clearly by Lowe ("Fl. Madeira" [1857], pp. 73, 74).

(*c*) The India name "suntara," for *C. nobilis*, is not a corruption merely of Cintra.

(*d*) The European words "lime," "lemon," are probably derived from Malay words.

(*e*) Huge forms of Citrus fruit may have risen from a fusion of two ovaries [p. 187, "My view would require that the Citrus fruit should have originated in *two* whorls of carpels, the outer or *rind-whorl* and the inner or *pulp-whorl*"].

(*f*) The true lime (*C. acida*, Roxb.) has more probably descended from *C. hystrix*, Kurz, than from *C. medica*, Linn.

(*g*) The juice-vesicles of the Citrus pulp are probably homologous with the oil-cells of the rind and leaves, and perhaps with the ovules.

It will be best to reverently draw a veil over the conclusions (*e*) and (*g*) and over the whole chapter on morphology. And the other five "conclusions," except (*b*), do not conclude anything. The foregoing is Dr. Bonavia's own summary of what he has proved, but he has done more than he claims; his account of his own horticultural observations is of value, and his deductions very generally correct. Of these only a few can be given here.

(1) The *Khatta* or *Karna* orange of Upper India produces two kinds of fruit on the same tree and on the same branch, viz. (1) the regular crop, of smooth oranges, ripe at the end of the dry season, and (2) the after crop, of grossly-warted oranges, ripe at the beginning of the rains.

(2) The European orange (*C. Aurantium*) is only known in India as a cultivated foreign orange, and is not common. It has been probably introduced into India in modern times—possibly from the West.

(3) The *C. nobilis* is the sweet orange of India; it has been in India from ancient times, and is possibly indigenous on the north-east frontier. It has only been brought to Europe in modern times. The Tangerine orange is a small form of it. (This *C. nobilis* is a more slender tree than *C. Aurantium*; its oranges are depressed at the poles; the rind is very full of large oil-glands, and separates easily from the pulp, which lies more or less loosely in the rind as in a bag.)

(4) The pummelo (*i.e.* Pompel-moes) of India and Ceylon is in flavour, structure of carpels, colour of pulp, &c., very distinct from the Syrian shaddock, *i.e.* the shaddock of English fruit-shops.

(5) In the plains of Upper India (Delhi, Lucknow, &c.) the Indian orange (*C. nobilis*) can be successfully cultivated, but requires irrigation (well-water being better than canal-water), budding, trenching, shade, special preparation of the soil by lime or manure, &c.

Every page of Dr. Bonavia's book offers opportunity of comment: the remaining space here available is devoted to the practical subject of the Indian sweet orange, *C. nobilis*, which we shall call the "Mandarin," and, for shortness, state first our own beliefs concerning it.

There are (according to Dr. Bonavia) three great centres of cultivation of the "suntara" in India, viz. (1) Sylhet, *i.e.* South Khasia; (2) Central India; (3) Delhi and Oudh. From Khasia (*fide* Bonavia) about 4000 tons, worth £4 a ton, are exported to Bengal, mainly to Calcutta. From Central India about 800 tons go by rail

to Bombay. The export from Delhi is small. Besides this many stations have a few orange orchards for local consumption—"a mere nothing."

It is evident from this that Khasia is the most important orange centre, and unfortunately Dr. Bonavia has had to treat this part of the subject second-hand. He hardly says anything about the Central Indian cultivation, except the remark (p. 127), "I do not know what the composition is of the black soil of the Central Provinces." This soil, which produces such excellent Mandarins, everybody knows to be disintegrated trap, *i.e.* the same soil which alone produces them in Khasia.

Dr. Bonavia spends much space in attempting to show that the suntara orange is not a Mandarin; he maintains that the suntara and Mandarin are nearly allied, and together form the distinct race (or species) *C. nobilis*. He admits that people in Ceylon and elsewhere *will* call the suntara the Mandarin, but he strongly denies that the Mandarin is a suntara; he may as strongly deny that the greengage is a plum. The best Khasi oranges run very close on the true Mandarin. The *C. nobilis* now grows as if wild from the hills of Southern China, probably to Assam (Khasia); it is also scattered along the outer Himalaya of Sikkim and Nepal. The centre of this area is almost certainly its "origin." Dr. Bonavia speaks of the Butwal (south of Nepal) orange as the sweetest orange in India: he has not tasted from the tree the Khasi orange at the end of January, which is considered *too* sweet by many Europeans. The Khasi orange is in fact larger than the Butwal; and for a *sweet* orange there is no finer in India or elsewhere.

Dr. Bonavia lays stress on the fact that the true Mandarin is when dead ripe a "varnished green," while the suntara is "from orange-yellow to lobster-red"; he found that the green oranges of Ceylon in travelling to Etawah (21 days' journey) had turned or were turning yellow; and he decides triumphantly that "the *green* orange has no *locus standi*." The fact is otherwise: the best Khasi oranges when dead ripe on the tree are an intense "varnished green." Picked somewhat unripe, and carried in a native boat (21–30 days) to Calcutta, they arrive a dull yellow or turning yellow. And perhaps Dr. Bonavia could prove by prolonging the journey that their true colour is black. The withered, unripe-picked, dull yellow, mawkish, Calcutta orange is a very different thing from the orange ripe on the tree above Chela.

The Mandarin grows best in steaming valleys just within the hills (and above all on disintegrated trap) at an elevation of 250–2000 feet: here it grows from seed without any trouble. In the plains, the fruit is worse the farther you recede from the hills, and great pains must be taken with the culture. Dr. Bonavia was unfortunate in having to experiment with the orange at Lucknow; free-trade principles would suggest that the most promising plan would be to improve the communications between the orange districts and the great centres of consumption. It was not the fault, however, of Dr. Bonavia that he had to try to grow oranges where they naturally will not grow. But Dr. Bonavia does not seem, with all the extensive cuttings in his appendix, to have got from the literature the help in his task that he should have got. He hazards, for example, a speculation (p. 116) that "the stock on which the Mandarin is grafted may have some influence"; apparently unaware that the regular practice is to graft the Tangerine on the common orange, as it then becomes a larger tree giving a more certain crop of larger fruit.

Quite apart from the question of oranges, it is well worth while to examine in some detail the method of Dr. Bonavia in obtaining information about the Khasi orange and its results, because it throws a flood of light on Indian reports in general. Dr. Bonavia appears to have tried three sources of information, viz. (a) a description of the orange-groves by Mr. Brownlow, (β) the answers to his questions returned by the Deputy-Commissioner of Sylhet, (γ) similar answers from the Rev. Jerman Jones. Dr. Bonavia does not refer to the "Himalayan Journals" of Sir J. D. Hooker, vol. ii; nor to Medlicott in Mem. Geol. Survey Ind., vol. vii. Art. 3. From these two latter sources, a very fair idea of the circumstances of the orange-groves of Khasia can be gained. Dr. Bonavia appears not to have the wildest notion of the country, climate, or soil.

Turning to Medlicott's map, we see that there are three large valleys (Chela, Umwai, and Sobhar), at the south extremity of the Khasi Hills, which are occupied by the "Sylhet trap." This trap extends in the Chela valley from the debouchement of the river at Chela up to 2800 feet at the head below Mamloo. This trap decomposes into a reddish earth, and there occur soft ashy beds very like forms of the Deccan trap. All three valleys are excessively steep, the undecomposed trap standing in huge masses. The rain-fall varies from 300 to 500 inches per annum. These valleys are thus rough and broken, and full of precipices inaccessible but by ladders and ropes. Intensely hot and steamy, and protected from winds, they exhibited a richer vegetation to Sir Joseph Hooker than he had seen in the Himalaya.

In the Chela valley, at the present time, the Mandarin orange occupies the whole area of the trap. The two other valleys are less completely occupied. There is also an orange-grove on a small trap area a few miles east, behind Jynteapore.

The Khasi cultivation is simple. The pips of the orange are raised without difficulty in a damp seed-bed, often in a nook shaded by a boulder of trap. A piece of the jungle is half cleared (*i.e.* most of the larger trees, some of the smaller); and the young orange-trees, 3–5 feet high, are stuck out promiscuously in the partial shade left; the root of each is pushed if possible under the heel of a block of trap. When the young trees have got hold enough to bear the sun, the *other* half of the jungle is roughly cut. The trees require no further labour. The orange-groves in the cold weather form a monkeys' paradise, and it is necessary to destroy these. Sometimes two or three villages unite, enclose the monkeys, and drive them down to an angle of the main stream, where they are slaughtered pitilessly. The sight of a single monkey is always sufficient to exasperate a Tyrna man to fury.

The crop is enormous; the river at Chela flows sometimes covered apparently with oranges. Before the season is half over, the pigs are so surfeited that their oranges have to be peeled for them. The valley has enormously increased in wealth in the last half-century. It is a Khasi saying that a man here may work for three days and eat for a month.

Now let us see what Dr. Bonavia says. He has the specimen soil collected by Mr. Brownlow analyzed by a trustworthy chemist, who finds no lime in it. Dr. Bonavia argues (p. 94) "that either Mr. Brownlow took his sample from one particular spot, or did not reach the calcareous soil." "Orange wood requires considerable lime. In Chela oranges grow very well; therefore the soil of Chela contains lime. Moreover, it is incredible as the district exports lime that no lime detritus is ever washed down by the floods which flood the orange-groves of Chela to the depth of 6 feet."

Nothing can be wider of the mark. Mr. Brownlow would have had to go very deep into the Sylhet trap, a very hard rock, to get any lime. It is true that there is limestone at Mamloo, and that the water that comes down has some lime in it—but very little. The floods at Chela rise sometimes 60 feet (instead of 6), but they cannot inundate even then much of the orange groves which run up to 2000 feet. Perhaps the most extraordinary statement in Mr. Brownlow's description is that (above Chela) "no vacancies are left in the planting of the orange-trees." The trap boulders are as big as cottages all over the valley.

We turn to the second source of information—the Deputy-Commissioner of *Sylhet*. Fifty years ago "Khasia" was attached to Sylhet, and known as North Sylhet; and the oranges are still known as Sylhet oranges. Dr. Bonavia applies, therefore, to the Deputy-Commissioner not of the Khasi Hills, but of Sylhet. The Deputy-Commissioner cannot possibly leave his own Sylhet government and his own station; but, being a very amiable man, he sends Juggaish Babu, Deputy-Magistrate of Chunamgunj, to collect the information for Dr. Bonavia. This gentleman commences his report, "I met with the greatest difficulty in compiling these statistics. The Khasis received my inquiries with suspicion, and tried to mislead me as much as possible." The Khasis would doubtless be most hostile to a Bengali Babu from Sylhet. But a Bengali Babu is not exactly the man to collect scientific information anywhere. Juggaish Babu commences, "The soil must be sandy." "The gardens being situated on river-sides, their soil naturally retains some moisture even in the dry season. Hence, perhaps, artificial irrigation becomes unnecessary." How the idea of the possibility of artificially irrigating the Chela valley can have occurred to the Babu's mind is marvellous; unless his report is in reply to some leading question by Dr. Bonavia.

"The garden is never hoed or harrowed before receiving the orange plants." It would not be possible to harrow such a country at any season. The Babu finally speaks of the land tenure. He does not mention the fact that Chela and its 12 associated villages form a republic under the protection of the English Government; their administrative Government consists of 4 councillors elected for four years by universal manhood suffrage. This constitution was established half a century ago by a Bengal civilian, and is unique.

We now turn to the third source of information to Dr. Bonavia, viz. the Rev. Jerman Jones, a missionary who has been in Khasia more than 25 years, and could have told much. But he appears only to have been consulted about the *names* of oranges in Khasi, and he replied that the name (for the Khasi Mandarin) is *U soh niam-tra*; which Dr. Bonavia writes *Usoh niamtra*; and states (p. 228) that *Usoh* is the generic Khasi name for oranges. [In a footnote, backed up by an appendix, No. 43, Dr. Bonavia carefully and amusingly notes that the word he got from the Deputy-Commissioner of *Sylhet* was *santra*, not *niamtra*. Dr. Bonavia evidently thinks the testimony of a missionary doubtful as against that of a Deputy-Commissioner. But the excellent Deputy-Commissioner in question has an extremely limited knowledge of Khasi, and would certainly not set himself up against Mr. Jerman Jones.]

Dr. Bonavia having got the word *usoh* for orange in Khasi, goes on to connect it with the Amboina words *aussi* and *ussi*. He proceeds (in tracing the origin of the Mandarin), p. 229:—

> "We have here, I think, something tangible to go by. The community of the generic name *usoh*, *ussi*, or *usse* to the Khasi Hills and the Malay Archipelago indicates, &c., &c."

In Appendix No. 58, the affinity of *usoh* is pushed further with the aid of Prof. Dr. T. de Lacouperie.

Now we come to the smash of the whole. *Soh* means "fruit" in Khasi, as see Hooker, "Himalayan Journal," vol. ii. p. 268, in note; in which language every noun *must* have the article prefixed, and *soh* being masculine, takes the masculine article U. Throughout Khasia, *usoh* so far from being the generic term for orange, would be understood to be *potatoes*. It is probable that, *at Chela*, if an Englishman pointed at a basket of oranges and said "*usoh*," they would guess which fruit he meant; but it is not Khasi. (Not the least curiosity in this book is that Mr. Jerman Jones should say that he had never found a Khasi who could offer the remotest suggestion as to the derivation or meaning of *niam-tra*. *Some* Khasis have an explanation; it might be worth Dr. Bonavia's while to ask Mr. Stevens of Chela, or Mr. Roberts of Nongsowlia, about it before publishing the corrected edition.)

The sum of the matter is that, if Dr. Bonavia had confined his book to his own observations and his own part of the country, with half a dozen plates showing properly the main types of Indian oranges, it would have been a handy inexpensive book of 200 pages at most. But, unfortunately, in Indian style, Dr. Bonavia's ambition has been to include all India in his book, to put forward his own extremely peculiar views of morphology, and to revel in linguistic and ethnological speculations, some of which are absolutely bad, and many of which can be but of little use. On top of the book thus weighted come the 120 pages of appendix, with the final result that the work bears a painful resemblance to the ordinary Secretarial Report, though it possesses really an amount of original observation and experience which such Reports often entirely want.

In one respect, Dr. Bonavia hardly comes up to the Secretarial Report: he spells, on one page, Shalla, Mhowmloo, Mostock, though those words were correctly spelt Chela, Mamloo, Mousto, as long ago as 1854 by Sir J. D. Hooker; or Dr. Bonavia might have referred to the fine map of the district by Godwin-Austen. Similarly, Dr. Bonavia states (p. 30), "The Bengalis have no *v* in their language." It is true that in vulgar

Bengali the *v* is often degraded into *b*—a linguistic change that runs from Hebrew to Spanish. But Dr. Bonavia might as well maintain there is no *h* in English because a Cockney pine-grower "eats is ouses by ot water."

Turning lastly to the question how far Dr. Bonavia's book assists the cultivation of the orange in India, we may doubt, with every admission of his horticultural skill and assiduity, whether he is on the right tack. The Khasi Mandarin can be grown almost without labour, and of a quality that is not likely to be approached by any horticultural skill and labour on non-volcanic soil in the plains. These oranges are now picked unripe, and occupy a month (often more) in reaching Calcutta in a native boat. A fruit-steamer would take them down in 2 or 3 days from Chattuck to the rail at Goalundo. Bombay would surely take many more oranges from Nagpore if the railway rates were lowered, and the "perishable fruit" accelerated in transit.

Mr. Medlicott made only a hurried march across the Khasi Hills when he laid in his three patches of Sylhet trap, and he only visited a very narrow strip of country. More of this trap certainly exists—perhaps at a low level, suitable for oranges; and the Government Geologist at Shillong might, in the cold weather, possibly discover some more patches. For the present, however, the known area of Sylhet trap is by no means nearly covered with oranges, except in the Chela valley, where the boundary of the orange-groves coincides very closely with the outcrop-line of the trap. C. B. CLARKE.

A NATURALIST AMONG THE HEAD-HUNTERS.

A Naturalist among the Head-hunters. Being an Account of Three Visits to the Solomon Islands in the years 1886, 1887, and 1888. By Charles Morris Woodford, F.R.G.S., &c. (London: George Philip and Son 1890.)

TILL within the last twenty years the Solomon Islands were almost unknown to Europeans, and their inhabitants were considered to be exceptionally uncivilized and treacherous. Whatever they may have been originally, they were not likely to be improved by their first contact with civilization, in the form of chance visits of whalers and vessels engaged in the "labour trade"—which in its early days meant kidnapping and slavery, often leading to murder or to wholesale massacres. With such experiences of the resources of civilization we are not surprised to hear from Mr. Woodford that they are "suspicious of strangers," or that they are "treacherous when they see their opportunity"; yet the fact that he lived among them for several months, often quite alone and unprotected, and that Mr. Lars Nielsen, a trader, lived on good terms with them for ten years, leads us to suppose that, under more favourable circumstances, their character might have been found to compare not unfavourably with that of the Fijians. There is now, however, no chance for them, as they are certainly doomed to speedy extinction. The numerous distinct tribes found on each of the islands live in a state of chronic warfare, incited by the ordinary causes of the quarrels of savages, intensified by a general mania for head-hunting and in some cases by the habit of cannibalism. So long as they fought with native weapons, spears and wooden clubs, the destruction of life was not very great; but the traders have armed them all with Snider rifles and steel tomahawks, the result being that entire villages and tribes are sometimes massacred; and this wholesale destruction, aided by infanticide and other causes, is leading to a steady decrease of the population.

The excellent reproductions of photographs with which the book is illustrated show that the Solomon islanders are typical Papuans, hardly distinguishable physically from those of the western and central portions of New Guinea. Their state of civilization appears to be about the same. They cultivate the ground assiduously, growing chiefly yams, taro, and plantains, and they even terrace whole hill-sides for the taro, a stream of water being admitted at the top, and conducted down from level to level with considerable ingenuity. As domestic animals they keep dogs, pigs, and fowls, and they had all these animals when first visited by the Spaniards in 1568. The dog Mr. Woodford believes to be the dingo of Australia; the pig the *Sus papuensis* of New Guinea; while the fowl was no doubt derived from the Malays. They build excellent canoes, fifty or sixty feet long, of planks hewn out of solid trunks, beautifully fitted together and fastened with rattan. Their houses are fairly built and comfortable; and they construct baskets, shields, wooden bowls, and various weapons and ornaments, with the usual savage ingenuity.

Mr. Woodford's chief occupation in the islands was the collection of specimens of natural history, and his account of the zoology of the group presents several points of interest. It is here we find the eastern limit of the marsupials, which are represented by a species of Phalanger hardly distinguishable from one inhabiting New Guinea. Bats are numerous, seventeen species being described, of which six are peculiar; and there are four species of native rats, one of which is the largest species known. About the two large rats, *Mus imperator* and *Mus rex*, Mr. Oldfield Thomas, who described them, makes the following interesting remarks:—

"It is, however, in their relation to each other that their chief interest lies, for they seem to be clearly the slightly modified descendants of one single species that, once introduced, has been isolated in Guadalcanar for some considerable time, while it has apparently died out elsewhere. Of this original species, some individuals would have adopted a terrestrial and others an arboreal life, and their respective descendants would have been modified accordingly. In this way I would explain the fact that at the present time we have in Guadalcanar two genuine species, agreeing with each other in their essential structure, and yet separated by a considerable number of characters, all having a more or less direct relation to a climbing or non-climbing habit of life. Of these, of course, by far the most striking are the broad foot-pads and the long rasp-like probably semi-prehensile tail of *Mus rex* as compared with the smaller pads and short smooth tail of *Mus imperator*."

This description well illustrates the fact of the importance of insular faunas as showing us how species may be modified under the least complex and therefore most easily understood conditions. On a continent the modification to an arboreal mode of life would have brought the species into competition with a number of other arboreal organisms, and would have exposed it to the attacks of a distinct

set of enemies, requiring numerous modifications of form, structure, and habits, the exact purpose of which we should have found it difficult to interpret. But here, where both competitors and enemies are at a minimum, we are able distinctly to see the few and simple modifications which have adapted the species to its changed mode of life. We have here, too, a case in which the isolation supposed to be essential in the production of new species has been effected solely by a change of habits within the same limited area, and it is evident that this mode of isolation would be equally effective in the case of a continental as of an insular species.

Lizards, snakes, and frogs are tolerably abundant, and the proportion of species peculiar to the islands is in the order in which they are here named; and this also indicates the increasing difficulty of transmission across an ocean barrier. Birds seem to be fairly abundant, parrots and pigeons forming the most conspicuous groups, while birds of paradise appear to be absent. Although insects decrease in number of species as we go eastward from New Guinea, yet two of the grandest of butterflies—*Ornithoptera Urvilleana* and *O. Victoria*—are found in the Solomon Islands, and were among the greatest treasures of Mr. Woodford's collections. The latter species was only known by a female specimen obtained by Macgillivray, the naturalist to the *Herald*, in 1854, till Mr. Woodford again found it in 1886, and discovered also the beautiful green and black male. Many fine Papilios are also found, among them a splendid blue and black species allied to the well-known *P. Ulysses* of the Moluccas. Here, as elsewhere in the tropics, some striking cases of mimicry occur, three species of Euplæa being so closely imitated by three species of Diadema, as to be undistinguishable on the wing; and each pair appeared to be confined to a separate island.

The following is an interesting observation on the habits of pigeons:—

"The small islands on the reefs are much frequented by pigeons. They resort to them during the day, but mostly towards sunset, when, at some islands that I know of, the pigeons may be seen arriving by twos and threes, or in flocks of ten or a dozen each, to roost on the islands, until each tree is crowded with birds. The only reason that I can assign for this habit is, that on these small islands the pigeons are freer from the attacks of the large monitor lizards that abound on all the large islands. I do not consider this at all a satisfactory reason, but it is the only one I am able to suggest. Certain it is that this habit of the pigeons plays an important part in the distribution of seeds from island to island. On any of these small islands the large seeds of the Canarium nut tree may be found, after being disgorged by the pigeons, while young trees in different stages of growth may often be seen."

Mr. Woodford's explanation of the pigeons' roosting on the small islands appears to be a highly probable one, and quite in accordance with other facts relating to this tribe of birds. They are exceptionally abundant in tropical archipelagoes, and most so in those where, as in the Antilles, the Mascarene group, the Moluccas, and the Pacific islands, arboreal carnivorous mammals are very scarce or altogether wanting. An analogous fact to that noted by Mr. Woodford is, that although the beautiful Nicobar pigeon has an enormous range, from the Nicobar Islands to New Guinea, it is almost unknown in the larger islands, especially in the western half of its area where mammals abound, but is more especially confined to the smaller islets and reefs, where it is comparatively free from enemies.[1]

Although the natives of the Solomon Islands are well supplied with Bryant and May's wax vestas in metal boxes—the only kind of matches that can be kept in the damp atmosphere—they still make fire in the native way, by friction, on certain ceremonial occasions, or at other times when matches are not forthcoming; and their method of proceeding is well described by Mr. Woodford. It consists in rubbing a hard piece of wood in a groove formed on a soft dry piece—the method used in the Moluccas and Australia—and he tells us that, though a native will usually produce fire in less than a minute, he has himself rubbed till his elbows and shoulders have ached without ever producing more than smoke.

The following extract gives a fair idea of the author's style:—

"It is amusing to see a mere child paddle alongside in a crazy trough of a canoe, only just capable of supporting its weight. The water splashes into the canoe at every stroke of the paddle, and at intervals the small child kicks it overboard with its foot—a novel kind of baler. Three or four mouldy-looking yams, ostentatiously displayed, are rolling about in the water at the bottom of the canoe. The unsuspecting stranger takes pity on the tender years, and apparent anxiety of the small native to trade, and gives him probably four times the proper price for his rusty yams. The child eagerly seizes the coveted stick of tobacco, and immediately stows it for safety through a hole in his ear, where at least it will be in no danger of getting wet. He next whisks aside a dirty-looking piece of matting that has apparently got accidentally jammed in one end of the canoe, and displays some more yams, of a slightly better quality than the last. For the sake of consistency you cannot well offer him less than you did before, and another stick of tobacco changes hands, and is transferred to the other ear. You think now that he must have finished, as there is no place in the canoe to hide anything else, but with a dexterous jerk that nearly upsets the canoe he produces a single yam that he has been sitting upon. How it managed to escape notice before is a puzzle. For this he demands a pipe, but is not satisfied with the first or second that is shown him. No; he must have a *piala tinoni* or have his yam back. The *piala tinoni* is a pipe with a man's face upon the bowl. But again the young trader is particular, it must also have a knob at the bottom or he will have none of it."

The book is well got up, well illustrated, and very pleasantly written. It is full of information as regards the natives, the scenery, and the natural history of these little-known but very interesting islands, and can therefore be confidently recommended to all who care for books of travel in little-known countries.

A. R. W.

OUR BOOK SHELF.

Recherches sur les Tremblements de Terre. By Jules Girard. (Paris: Ernest Leroux, 1890.)

THE scientific study of earthquake phenomena has of late years made great progress, and we are glad to welcome a book which brings together the new matter

[1] See "The Malay Archipelago," p. 350.

which has hitherto been published only in various Journals and Transactions of Societies. The book commences with a chapter on ancient traditions, giving a chronological table of the more important shocks which have occurred since 79 A.D. The second chapter briefly discusses the connection between earthquakes and volcanoes, a subject of which we have apparently a good deal still to learn. Then follow descriptions and illustrations of various seismometers and seismographs, including the latest forms devised by Profs. Gray and Milne. In this chapter there are given several interesting comparisons of earthquake curves automatically recorded by the instruments, and curves artificially produced by the application of forces of known direction and magnitude. The propagation of shocks through land and water, and their destructive effects, are also considered, the latter being illustrated by sketches of some of the more remarkable fractures and displacements which have been observed. The last chapter summarises the suggestions which have been made as to possible connections between earthquakes and astronomical and meteorological phenomena. In conclusion, M. Girard points out the necessity for continued systematic observations, and enumerates the chief points on which further information is required.

To those who know little or nothing of the subject, M. Girard's little book will form an admirable introduction; and to the initiated it will be a handy book of reference to its latest developments.

La Photographie à la Lumière du Magnésium. By Dr. J. M. Eder. Translated by Henry Gauthier-Villars. (Paris: Gauthier-Villars and Son, 1890.)

THIS is a translation of a very interesting little German work on the employment of magnesium light for the purposes of photography, and will form a useful addition to our photographic literature. The author first gives a brief account of the earlier stages of the subject, taking us back to the time when Bunsen and Roscoe, in the year 1859, indicated the considerable advantages the light of magnesium presented for photo-chemical studies and lighting. He then shows how Crookes afterwards employed the light for photographic purposes.

Amongst the very first attempts of artificial lighting, the wire of magnesium was used. It was burnt in a specially-made lamp, and the light thus produced answered fairly well for interiors, but was useless for portrait work, being too harsh. The next advance was the employment of a mixture consisting of the powder of magnesium, chlorate of potassium, and a sulphide of antimony; the light was produced by igniting the mixture, which flared up instantaneously. The chief drawback to this method was the great precaution that had to be taken during the mixing, as the slightest blow caused an explosion. Saltpetre in place of potassium was sometimes used so as to lessen the chances of explosion.

The methods described in chapters v. and vi. were those which gave the best results. They consisted in blowing powdered magnesium through a tube and allowing this powder to come out at the other extremity into a gas or candle flame; the light thus produced was extremely actinic, and did not present any danger. The lamps of Schirm and Loehr, illustrations of which are given in these chapters, were on this principle, and gave great satisfaction for portraiture, being worked by means of a pneumatic india-rubber ball. Chapter vii. treats of the combustion of magnesium in oxygen, and in it is described Piffard's apparatus for the production of this light, which was found to be enormously increased by the presence of the oxygen. The remaining chapters deal with methods of taking groups by this artificial light; and there is a very interesting illustration of the pupil of the human eye, photographed in a dark room by means of the flash light, the exposure of which was so short that the pupil had no time to contract. The book concludes with some hints on the precaution necessary to insure successful development of the negatives taken by these processes, and with a short appendix by M. Alexandre.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Panmixia.

BUT for his statement that I "cannot be sincere," I should not have deemed it necessary again to answer Prof. Lankester; anyone who is read in the literature of Darwinism must already have perceived that a further reply on my part is needless. An accusation of insincerity, however, ought not to pass unnoticed; and therefore I will ask your more general readers to observe the ground on which it has been made.

In my answer to his original criticism I endeavoured to show that Prof. Lankester "fails to distinguish between the cessation and the reversal of selection," or, more particularly, between panmixia and the economy of growth; and this is the point with regard to which insincerity is charged. Yet this is just the point—and the only point—in dispute. I have always represented that the cessation of selection is *per se* a cause of degeneration, whether or not it be associated with the economy of growth. Prof. Lankester, on the other hand, represented that the cessation of selection is not *per se* a cause of degeneration; but merely a "state," which is precedent to, and contemporaneous with, the economy of growth—the latter being the cause, while the former is but a condition to the occurrence of this cause. Such, at any rate, appeared to me the only meaning that could be gathered from his paragraph at the top of p. 488; and it is now over and over again repeated in his last letter. For instance:—"Cessation of selection *must be supplemented by economy of growth* in order to produce the results attributed to 'panmixia.' And inasmuch as economy of growth as a *cause* of degeneration involves the *condition* of cessation of selection, Mr. Darwin *in recognizing the one recognized the other*. . . . It is true that Mr. Darwin did not recognize that such unrestricted variation must lead to a diminution in size of the varying part *without the operation of the principle of 'economy of growth.'* This was no strange oversight: *he would have been in error had he done so*. . . . The term ['panmixia'], like its correlative 'cessation of selection,' *does not indicate a principle, but a natural condition:* it does not involve the inference that a dwindling in the size of the organ must result from inter-breeding; but *simply points to a precedent condition*" (p. 559: italics mine).[1]

Where, then, is the insincerity in saying that Prof. Lankester does not perceive the distinction between the cessation of selection and the economy of growth as two totally different causal "principles"? Or what remains for me but to repeat, with all sincerity, "he confounds the 'idea' of panmixia with that of the economy of growth," and "fails to perceive the 'essence of the idea' in the all-important distinction between selection as withdrawn and selection as reversed"?

It is true that at the close of his last letter Prof. Lankester admits, "when we consider shape and structure, and not merely size, it is clear that panmixia without economy of growth would lead to a complete loss of that complex adjustment of parts which many organs exhibit, and consequently to degeneration without loss of bulk." But how was it possible to surmise from his first letter that he had in his mind such reservations as to "shape" and "structure?" Or, indeed, how is it possible to reconcile such reservations with the passages above quoted from his last letter, to the effect that the cessation of selection is "not a principle at all," but merely "a condition which alone cannot produce any important result"? Are we to conclude that in Prof. Lankester's opinion neither "a complete loss of complex

[1] I may remark that the term "cessation of selection" is not the "correlative," but the *synonym* of the term "panmixia." And I may further remark that the term "reversal of selection" is not, as Prof. Lankester supposes, the synonym of the term "economy of growth." Economy of growth, where useless structures are concerned, may determine a reversal of selection; but the reversal of selection may also be determined by many other causes and conditions, which are equally potent—or even very much more potent—in this respect.

adjustment," nor any amount of change as to "shape," deserves to be regarded as "any important result"? Must we not rather conclude that when he first wrote upon "the state of panmixia," he had not sufficiently considered the subject; and, in now endeavouring to trim, ends by contradicting himself?

The only issue being as to whether panmixia is itself a cause, or merely the precedent condition to the occurrence of a totally different cause, nothing more remains to be said. As a result of his further consideration, Prof. Lankester now admits "it is clear" that, "without economy of growth," panmixia *is* a cause of degeneration where "shape" and "structure" are concerned. And, when he considers the matter a little more, he will doubtless perceive the contradiction in saying that, where degeneration as to "size" is concerned, "it is absurd to attribute the result, or any proportion of it, to the panmixia or cessation of selection alone." Variations round an average mean occur in "size" or "bulk," just as they do in "shape" and "structure": therefore, if on this account panmixia is conceded to be a true cause of degeneration as regards the latter, it must likewise be so as regards the former. The fact that in the former case—as I showed in 1874—it must always be more or less associated with the economy of growth, is no proof that it then loses its due "proportion" of causal agency; while, with the now single exception of Prof. Lankester, everyone who has since written upon this "principle" takes the same view as I did—viz. that the phenomena of "dwindling" in our own domesticated animals furnish as good evidence of the operation of panmixia as is furnished by the other forms of degeneration to which he now alludes. Therefore, if he really believes it is in this case "absurd to attribute the result, or any proportion of it, to the panmixia," he becomes opposed, not only to me, but to Galton, to Weismann, to Poulton, and to everybody else who has ever considered the subject. In short, it is now a matter of general recognition that what he calls my "unreal separation between 'cessation of selection' and 'reversal of selection,'" is a separation so fundamentally real, that it is the means—and the only means—of abolishing the evidence of Lamarckian factors where this once appeared to be most conclusive; seeing that "with highly-fed domesticated animals *there seems to be no economy of growth, nor any tendency to the elimination of superfluous details*." [1]

April 19. GEORGE J. ROMANES.

IN NATURE of April 3 (p. 511) Mr. Herbert Spencer suggests an interesting subject for discussion on the effects of use and disuse of organs, asking for an explanation on the theory of panmixia of the well-known tendency of domesticated animals to droop the ears. Many of the ruminants in a wild state have their ears set on horizontally with an inclination to droop; for instance, the gnu, sable, antelope, zebu, gaur (Central India), Cape buffalo, &c. The American bison has completely drooping ears; there is also at the Natural History Museum, South Kensington, in Case 57, a specimen of a smooth-haired sheep from Turkey in Asia, *Ovis aries*, which has dependent ears. Pathologically, though as yet not physiologically proved, the discussion of the transmission of acquired characters possesses a deep interest.

Evolution seems impossible without variation, and until the latter can be explained on other grounds than those of the inheritance of accumulated minute changes in character acquired through ages of slowly varying climate and conditions of life, preserved by natural selection, this transmission would seem a reasonable conclusion so long as the characters acquired were of service to the inheritor in the struggle for existence.

Though Weismann disbelieves most of the evidence Darwin collected on heredity, and doubts the possibility of the communication of external influences by the somatic cells to the germ cell, he suggests no other hypothesis to account for the phenomena of change, beyond the vague expression "predisposition of the germ-plasm." R. HAIG THOMAS.

April 5.

[1] Darwin, "Variation. &c.," ii. p. 289. Seeing the importance of "the idea of panmixia" in this connection, I must still be permitted to regard it "unfortunate" that it was not present to Mr. Darwin's mind before the publication of his last edition of the "Origin of Species." But this does not mean, as Prof. Lankester "affects to suppose," that I regard the unfortunate nature of such a circumstance as due to the fact that I happened to be the first who perceived it. One can only assign so petty a form of "*badinage*" to the same argumentative level as "pointing out the oversight" that in my first letter I "omitted to credit Mr. Darwin with the recognition of the economy of growth." Prof. Lankester has committed about as grave an oversight in his own letter, by omitting to credit Mr. Darwin with the recognition of natural selection.

The "Rollers" of Ascension and St. Helena.

YOU probably know that the United States Scientific Expedition under Prof. Todd has had occasion to stop here during the past two weeks. I have resided during this time continuously at the signal station on Cross Hill (altitude 870 feet), studying the clouds and winds with many important results. I have had an excellent opportunity to observe the "rollers" for which Ascension and St. Helena are famous, and I have been able to demonstrate convincingly to myself their nature and origin. I should be obliged to anyone who will tell me whether my following views have perhaps been arrived at by previous observers.

The south-east trade blows with very various intensities over different parts of the South Atlantic, and the regions of light trade, no trade, fresh and strong trade, vary from day to day, as shown by comparing the logs of vessels. A limited region of strong south-east trade is a region whence spreads in all directions the corresponding strong south-east swell of the ocean surface—very distant storm winds or very near regions of high south-east winds produce similar results on the ocean swell: the locality of these winds will determine whether any point shall be experiencing a light or heavy swell. What causes the variations in the south-east trades, and in what direction the regions of strong trade move, are questions for further study. My present data would show that these latter regions move against the trade winds, *i.e.* from Ascension towards St. Helena, but there need be no uniformity in this respect.

Now if a south-east swell surrounds such an island as Ascension it is not directly felt on the lee side, but the long rectilinear swells, that advance faster in deep than in shoal water, are seen from my elevated station to assume the new curved shapes that result from the retardations on the shoals. So that finally in typical cases we have off the lee of the island a series of crossing and interfering swells producing at one point a quiet spot, at the next a double swell and great breakers.

The rollers are a magnificent example of deflection by shoals, and of interference and of composition of waves. Their severity at St. Helena and Ascension is apparently due to the proportions of the dimensions of the swell to that of the islands, just as in the interference phenomena of sound and light everything depends on the size of obstacle and length of wave. I have a number of measures that will, I hope, enable me in the future to give more accurate details, but for the present I can only inquire as to the bibliography of the subject. The correct explanation of the rollers, and of the swell on the West African coast, will undoubtedly lead us to further steps in marine meteorology. CLEVELAND ABBE.

U.S.S. *Pensacola*, Ascension, April 2.

Self-Colonization of the Coco-nut Palm.

WITH reference to Mr. Hemsley's note on this subject to NATURE (p. 537), I regret to have to inform him that the two young palms found on Falcon Island were placed there by a Tongan chief of Namuka, who, in 1887, had the curiosity to visit the newly-born island, and took some coco-nuts with him. This information I received from Commander Oldham, who had been much interested at finding these sprouting nuts at some 12 feet above sea-level and well in from the shore of the island, but who found out the unexpected facts in time to save me from making a speculation somewhat similar to Mr. Hemsley's.

W. J. L. WHARTON.

Nessler's Ammonia Test as a Micro-chemical Reagent for Tannin.

IN most cases the presence of tannin is immediately shown by all the ordinary reagents used by the botanist for its discovery. This does not happen sometimes, however; as, for instance, in the tannin-cells found in the epidermis on the dorsal side of the leaves of some plants. As a good typical example the common primrose may be cited. Of all the ordinary tests, including iron salts, potassium bichromate, Möll's test (copper acetate and iron acetate), ammonium molybdate, and osmic acid in 1 per cent. solution, the latter alone acts immediately upon the tannin in the primrose leaf's epidermis. It may hence be worth while recording the discovery of a second reagent capable of acting rapidly and effectively; and one which is easily made and will keep for some time should be especially valuable. Such a reagent is Nessler's test for ammonia.

Nessler's test is made, as all the world knows, by saturating a solution of potassium iodide with mercuric iodide, and adding an excess of caustic potash. Ammonia gives with this a reddish precipitate; tannin a brown, and when in considerable quantity a deep black one; but if little tannin be present, the brown may tend towards purple. It goes without saying that much experiment must be undertaken before one can be sure of the substance giving the brown precipitate being really tannin. To be conclusive, such experiment should be carried out in four different directions:—

(1) The reaction ought to be given in all cases when the ordinary reagents make their presence immediately felt.

(2) Cells which will not immediately give the tannin reaction with ordinary tests, but which will do so with Nessler's test, must also do so under the former conditions if time be allowed.

(3) Tissues which will not yield the reaction with Nessler's test, must not give it with any other reagent even after the lapse of some time.

(4) Solutions of tannin must give a brown precipitate with Nessler's test.

Under the first of these headings may be mentioned growing shoots of the garden rose. On laying a radial longitudinal or a tangential section of this in Nessler's fluid a copious black-brown precipitate is obtained, and the same thing occurs with the beautiful tannin-sacs of *Musa sapientum*. In all other instances where tannin has betrayed its presence by the use of ordinary reagents, the brown colour has been obtained upon treatment with Nessler's test.

The primrose leaf may be again cited as an example of the time sometimes necessary to show up tannin with the usual reagents, of which it must here suffice to particularize ammonium molybdate. On laying in the molybdate a small piece of epidermis torn off the lower side of the leaf, one first sees a cell here and there coloured the characteristic and beautiful yellow given by this test: these coloured cells are usually situated among the elongated more or less rectangular cells overlying the vascular bundles. Re-examination after half an hour or so shows several more of the cells similarly coloured, but it is usually not till after a couple of hours that one can safely declare all the tannin-containing cells to have been stained. With variations in respect of time, and with the sole exception of osmic acid, all the other tests act in precisely the same way; even Möll's, preferred to all others by some of our Continental *confrères*, being as unsatisfactory as the rest. But sooner or later its characteristic colour is imparted to these cells by every reagent, thus proving tannin to be present.

For the negative experiment—the absence of the brown colour from tissues treated with Nessler's fluid, and its absence from the same tissues when acted upon by ordinary tannin reagents—recourse was again had to epidermis. The experiment succeeded in all cases: among these may be cited *Fatsia japonica*, wallflower, box, *Stellaria media*, and *Pelargonium zonale*. In none of these did tannin show up, although twenty-four hours were allowed to elapse before the preparations were destroyed.

Lastly, Nessler's fluid gives a rich brown precipitate with solutions of tannin. Moreover, with gallic acid a grey-green one is thrown down, thus affording an easy means of distinguishing between these bodies.

For these reasons, therefore, viz. the rapidity, certainty, and distinctness of its action; the ease with which it can be made; its permanence when made; and lastly, the difference in its behaviour towards tannin and towards gallic acid—for these reasons I am bold enough to anticipate the time when, to adapt a hackneyed expression, Nessler's fluid will be regarded as a reagent which no botanical laboratory should be without.

SPENCER MOORE.

The Moon in London.

SOME years ago a weekly paper represented a young rustic asking his mother, "Be that the same moon they have up to Lunnon?" to which question the mother evasively replied, "You leave the moon alone and go to bed." The boy was satisfied by retorting, "I baint a touching on it." But his question is this month brought once more to the front by the following passage, which will be found in one of our most important monthly magazines. "But if," says the writer, "there is an abuse of the deductive method of reasoning, there is also an abuse of the inductive method. One who refused to believe that a new moon would in a month become full, and, disregarding observations accumulated throughout the past, insisted on watching the successive phases before he was convinced, would be considered inductive in an irrational degree." We cannot, of course, presume to dictate to or for the moon "up to Lunnon," but here in the country the new moon becomes full in half a month, and we have convinced ourselves by watching the successive phases that a new moon will in a month become a new moon again. Nevertheless we willingly admit that life is far too short and too encumbered to allow of any man's repeating more than a small fraction of the accumulated observations on which his scientific beliefs are founded. Yet, on the other hand, taking things for granted is probably the source of nine-tenths of the errors that fill our minds, while the men of genius seem to be just those who know best what and how to observe for themselves, and how much to trust in the observations of others.

Tunbridge Wells.

Foreign Substances attached to Crabs.

THERE is, of course, no analogy between whiffing for mackerel with red flannel, and fishing for cod on the bottom with any kind of bait.

If Actinians are offensive to fish, it is a singular fact that, when a cod-line is baited with mussels, herring, sand-eels, and anemones (viz. *T. crassicornis* and *A. mesembryanthemum*), the latter prove by far the most successful baits.

Impalement on a hook by no means kills an anemone, whose powers of offence are, perhaps, little lessened thereby; and under natural conditions the tentacles are not always expanded. Though the full-grown cod does not affect the tidal waters of the coast, yet the "rock" cod, by no means the youngest of its species, ventures close inshore; and the largest cod abound amongst the tidal waters of the Bell Rock.

The cnidæ of an anemone seem very efficient weapons against a soft-skinned Cephalopod, but they are not necessarily so against a tough-skinned fish.

Prof. McIntosh, in the work referred to in a previous letter, records *Tealia* and *Peachia* from the stomach of the cod, and *Edwardsia* (in swarms) from that of the flounder. He also informs me that he has found *Stomphia* in the stomach of the cod. I may add that the practice of baiting here with anemones is much more recent than the work referred to.

Of all British Cœlenterates, *Cyanæa* is, perhaps, the most deadly; yet many trustworthy observers have found young cod sheltering themselves beneath its umbrella—a fact which seems to indicate that they hold its stinging powers in some contempt; and Dr. Collingwood, in "A Naturalist's Rambles in the China Seas" (p. 150), has recorded the discovery of an immense fish-sheltering anemone.

ERNEST W. L. HOLT.

St. Andrews Marine Laboratory.

The Relative Prevalence of North-east and South-west Winds.

IN a note at p. 470 (NATURE, March 20), attention is drawn to the statement by Mr. Prince contained in his meteorological summary of observations taken at Crowborough, Sussex, in 1889, concerning the greater prevalence of north-east as compared with south-west winds which he finds to exist in recent years. The writer of the note mentions that this is not borne out by the Greenwich observations, but some definite statistics as regards Greenwich, and distinct comparison with the Crowborough numbers, may perhaps not be unacceptable to your meteorological readers.

Mr. Prince remarks that in previous years he finds only two years in which north-east winds have been in excess of south-west. In the first, 1864, the days of north-east wind were 104, of south-west wind 89; in the second instance, 1870, the days of north-east wind were 107, of south-west wind 88. The corresponding Greenwich numbers were, in 1864, 43 and 108; and in 1870, 65 and 96.

On the average of the years 1859 to 1883 Mr. Prince gives north-east wind on 63 days, south-west wind on 99 days. The corresponding Greenwich values are 43 and 111 respectively. For the years 1885 to 1889 he gives the average frequency of different winds as follows, to which I have added the values for Greenwich. C. indicates Crowborough, and G. Greenwich.

	N.	N.E.	E.	S.E.	S.	S.W.	W.	N.W.	Calm.	
C.	41	102	21	22	38	72	50	17	—	days.
G.	49	52	35	23	37	100	40	19	10	days.

He further gives the averages for 47 years, to which I have added those for Greenwich for 49 years.

	N.	N.E.	E.	S.E.	S.	S.W.	W.	N.W.	Calm.	
C. (47 y.)	33	63	29	27	28	91	59	35	—	days.
G. (49 y.)	40	45	27	22	35	106	46	22	22	days.

The Greenwich values are determined from numbers derived from the records of the self-registering Osler anemometer of the Royal Observatory as given in the annual Greenwich volumes. The preponderance of south-west wind over north-east seems to have been, throughout, less at Crowborough than at Greenwich. But it is only in recent years that the difference has become so pronounced, the Crowborough numbers for each year 1885 to 1889 being largely in excess for north-east wind, whilst the Greenwich numbers are greatly in excess for south-west, as in former years. At Greenwich during the first 24 years of the 49 years series, the average number of days of north-east wind was 46, of south-west wind 107; during the last 25 years, of north-east wind 44, of south-west wind 106.

It would be very interesting if a similar comparison could be made with some other station in the south of England.

Greenwich, April 16. WILLIAM ELLIS.

Science at Eton.

IN the *Illustrated London News* for March 29 I find an account (with illustration) of an astronomical lecture at Eton. It appears that the scholars "were allowed" to listen the other day, in the new lecture-room, to a lecture by Major-General A. W. Drayson, R.A., on the second rotation of the earth and its effects.

General Drayson has written some books on this subject which possibly no one has answered, for the simple reason that they answer themselves; but it seems now, that he is permitted, under the auspices of their teachers, to urge his paradoxes on the students of our largest public school.

Is Eton without any science teacher? or is the so-called teacher incapable of preventing absurdities being put forward with authority? Are the lecture-rooms of Eton College open to "Parallax" and the circle-squarers? J. F. TENNANT.

MODIGLIANI'S EXPLORATION OF NIAS ISLAND.

ABOUT two years ago, on his return to Florence, I gave a brief account of Dr. Elio Modigliani's very successful and interesting exploration of Pulo Nias (NATURE, vol. xxxv. p. 342). We have now before us the general results of that exploration, embodied in a portly volume most elegantly got up, rich in maps and illustrations, and, what is better, full of interesting facts, carefully collated notices, and well pondered and carefully drawn deductions; in short, one of the best books of its kind.[1]

Judging from what he has done, Dr. Modigliani is evidently made of the stuff which produces the best explorers. Resolute and persevering, moved by what we in Italy call *il fuoco sacro*, ever ready to put up with privations of all kinds, although accustomed to a very different sort of life, a quick and keen observer, he has indeed done wonders; and considering that he has not had the advantage of any special training in natural science, he has shown himself to be a good geographer and ethnologist, and a clever naturalist.

Dr. Modigliani's choice of the island of Nias as the field of his explorations was a singularly happy one, in which he was guided by no less a man than Odoardo Beccari. Few indeed of the hundreds of islands of that wonderland, the Malayan Archipelago, present such an accumulation of interesting problems as Nias. Lying off the ocean seaboard of Sumatra, and partaking naturally of the characteristic features of its big neighbour, it has a flora and fauna with a remarkable number of special characteristics, whilst its human inhabitants show strange affinities with people of other races and of distant lands.

I shall now endeavour to give a concise account of Dr. Modigliani's exploration of Nias, and of the results he obtained, as given in his book. Dr. Modigliani left Italy at the end of 1885; he paid a rapid visit to India, crossing overland from Bombay to Calcutta, *viâ* Delhi and Agra, and visiting Darjiling; he touched at Rangoon, and after a short stay at Singapore and a lengthened one in Java, where at Batavia and Buitenzorg he prepared his local equipment, and engaged Javanese hunters and collectors, he reached Siboga, Sumatra, early in spring, 1886. Thence he started for Gunong Sitoli, the only civilized port of Nias, on one of the Dutch Government *Kruis* boats on April 14. Dr. Modigliani spent five months on the island, which he left in the middle of September. On his way back to Italy he completed the tour of Sumatra, touching at Kota Rajah and Olelek (Acheen), visited Singapore again, touched at Colombo, and crossed India a second time from Madras to Calicut, visiting the Todas and some of the hill tribes of Southern India, which had a special interest for him in his researches on the origin and affinities of the people of Nias. Dr. Modigliani brought back with him from Nias extensive and important collections—ethnological, zoological, and botanical—and whilst these were being studied by specialists, he actively set to work arranging and sorting his notes and the material for his book. Undertaking to deal with all the ethnological part himself, he visited the more important ethnographical museums of Europe, and even the minor ones where he knew that specimens from Nias were to be seen. To complete his historical and geographical researches regarding Nias, Dr. Modigliani paid a lengthy visit to Holland, working in the Libraries and Government Archives at the Hague and Leyden. I, who have had many opportunities of observing and admiring his untiring energy and activity, could hardly feel surprised, on reading his book, to find it so full of information and so excellently well done.

Dr. Modigliani has divided his work on Nias into two parts. The first contains three chapters, and is entirely introductory and historical; the second, in twenty-three chapters, with appendices and bibliography, contains the narrative of his sojourn in Nias, and his own personal observations and studies on men and things in that island. I have little to say on the first part of Dr. Modigliani's book except that it embodies the results of much erudition and careful and patient collation. From the earliest semi-fabulous notices of Al-Neyan, El-binan, Neya, Niha, Nia, in ancient Arabic and Persian manuscripts, we are brought to European intercourse with Tano Niha, as the natives call their island, and thence on through the modern vicissitudes of Dutch domination, which to this day is little more than nominal, except at Gunong Sitoli and in the northern portion of the island, where, however, German missionaries appear to have done more to spread the influence of civilization than the colonial authorities.

Part II. occupies by far the greater portion of Modigliani's bulky volume. After telling us how he travelled to Nias from Siboga—an adventurous crossing with a Malayan crew, a bad boat, and dirty weather—Dr. Modigliani devotes a chapter to the geography, meteorology, and geology of Nias. The island is hilly, but can hardly be called mountainous. A notable feature is the frequency of earthquakes, easily explained by the proximity of the volcanic chain of Sumatra. Rivers and watercourses are numerous, but few are of notable size. Geologically, Nias is evidently of recent formation; a collection of rock samples brought together by Dr. Modigliani might have shed much light on this interesting subject, but it was unfortunately lost. Madreporic limestone and clams (*Tridacna*) were noted on the hill-tops; true lignite has, however, been found in various parts. The Dutch colonial authorities deserve much praise for their

[1] Elio Modigliani, "Un Viaggio a Nias." Illustrato da 195 incisioni, 26 tavole tirate a parte e 4 carte geografiche. Pp. xv.-726. (Milano: Fratelli Treves, 1890.)

widely-spread and efficiently organized service of meteorological observations; even in the less important stations these are regularly recorded, and this has been the case for a long series of years at Gunong Sitoli. This is at present the residence of the Dutch civil and military authorities in Nias; the principal magistrate is a *Controleur*, who, with the officer in command of the native garrison, the medical officer, and the missionaries and their wives, form the sum-total of the European residents at Nias. Gunong Sitoli is mostly peopled with Malays, Klings, and Chinamen, the trade of the island being chiefly in the hands of the latter. Here, overcoming not a few serious difficulties, Modigliani made his preparations for visiting the southern parts of Nias, freer from external contact, and therefore more interesting; and for this purpose, a Malay boat—*pencialàng*—was chartered. Whilst these preparations were being completed, Dr. Modigliani visited a large cave near Hili Sabegno, and, besides other interesting animals, collected specimens of a bat (*Emballonura semicaudata*) previously known only from Polynesia. Meanwhile, his hunters were not inactive, and, amongst other interesting specimens, four new species of birds, a singular new earthworm, and several new insects were collected in the neighbourhood of Sitoli; the birds have been recently described by Salvadori as *Gracula robusta*, *Calornis altirostris*, *Miglyptes infuscatus*, and *Syrnium niasense*.

Tobacco is the principal article for barter with the wilder inhabitants of Nias, therefore Modigliani provided himself with a large stock, mostly Sumatra grown, and called *mussi*; Javanese tobacco, called *giau*, has a greater value. He provided himself, besides, with cotton cloth of different colours, and brass wire, also much sought by the Nias people.

At last the *pencialàng* was ready, and Modigliani sailed in her to the south end of the island, and anchored in the Luàha Vára Bay. His first sight of the Nias Southerners was rather forbidding, and seemed to confirm decidedly the many stories he had heard of their indomitable hostility and ferocity. A large number of warriors, armed with lances and rattling their big shields with a peculiar movement of the hand on the forearm, crowded on the beach at his landing, to the no small alarm of his followers. With much pluck and presence of mind, Modigliani overcame the momentary anxious suspense, and in a few minutes he was on his way to the village of Bàwo Lowaláni, surrounded and followed by the excited warriors. Here he soon made friends with Faòsi Aro, the chief, the tallest and most crafty of Southern Niassers, who appeared with two immense ear-rings resting on his right shoulder. A liberal distribution of tobacco soon made Modigliani popular all round. Bàwo Lowaláni is a good type of a South Nias village, placed on a height and defended by a stout stockade; the incessant wars between village and village render such precautions necessary. Our traveller passed several days here, having taken up his quarters in the house of Faòsi Aro, built as usual on stout piles; he was thus able to gather much information on the ways and manners of the Niassers. His Javanese collectors, although much afraid of the natives, who were constantly armed and on the alert, being then at war with two neighbouring villages, did some good work, and some new and rare insects and a new species of bird (*Cittocincla melanura*, Salvad.) were added to the collections.

At Bàwo Lowaláni, Dr. Modigliani received a special invitation to visit Hili Dgiòno, a village further inland to the west. A deputation awaited him outside Bàwo Lowaláni, not trusting themselves inside; a live fowl packed in a singularly neat manner (see Fig. 1) was presented to him, and the knife of the chief of Hili Dgiòno—the latter to be returned. Faòsi Aro did all in his power to dissuade Modigliani from going, telling him he would certainly be killed, as the Hili Dgiònans were a bad lot; but our traveller decided to keep his promise, and the evening of the next day saw him at Hili Dgiòno, where he met with a most cordial reception, especially from the old chief, Sidúho Ghèo. At this place Modigliani passed pleasant days, was able to take a fine series of photographs, and saw more of the natives and learnt more of their customs than anywhere else. The women alone, as in most parts of Nias, kept aloof, and would not be photographed. Here Modigliani saw palpable proofs of the well-known head-hunting propensities of the Niassers. The big council house, or *osalè*, was adorned

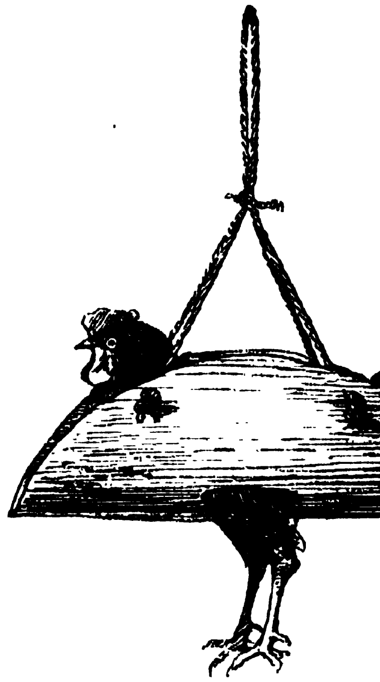

FIG. 1.—How a fowl travels.

with numerous skull trophies, hanging under the low roof. Heads are taken not only in war, but on many other occasions, for reasons amply given in Modigliani's book, most of which are similar to those which send the Dayaks of Borneo on their head-hunting expeditions; neither age nor sex are spared. No youngster in Nias is proclaimed a man and a warrior until he has cut off a head; he then assumes the prized *calabúbo* (Fig. 2), a beautiful collar made of thin circular sections cut out of the double nut of the *Lodoicea seychellarum* (which is often cast by the sea on the island), neatly strung on a brass wire with a circular

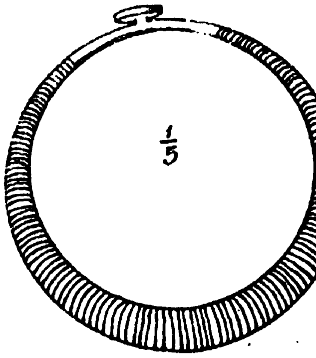

FIG. 2.—A *calabúbo*.

brass disk at the junction. The sections of the nut diminish gradually from about an inch in diameter to less than half at both ends, where the circular collar is closed with the disk; they are polished so as to present a uniform surface. None of the trophy skulls seen by Dr. Modigliani were in any way ornamented, but in his book he gives the drawing of a very singular one with artificial hair, beard, and ears, communicated by the late Baron von Rosenberg, who saw it in a house in Nias; I should fancy that it represents a European (Dutchman), for the beard hardly grows on a Niasser's chin in such luxuriance

(Fig. 3). When old Sidúho Ghèo heard that Modigliani desired skulls (for his anthropological collection), he of course concluded that he wanted to get fresh ones as trophies, and at once offered to organize an expedition

FIG. 3.—Ornamented trophy skull.

with chosen warriors; he would not give away any of those hung under the *osalò*.

At Hili Dgiòno, Modigliani was able to add largely to his ethnological collections, especially weapons. The defensive armour of the Niassers is peculiar. Formerly they made singular helmets of rotang and arenga-fibre, with beard and mustachios; now the chiefs are provided with curious iron helmets, pot-shaped, ornamented with a large plume or palm-leaf cut in a thin iron lamina, usually gilt; they wear, with this, curious iron spur-like mustachios passing under the nose and secured to the ear. The head-dress of the warrior of "old Japan" was a very similar contrivance; to complete the parallel I will add that the ceremonial war-jacket, often a regular cuirass in buffalo-leather, pangolin-skin, and scales or twisted rope tissue of tough *Gnetum* fibres, usually projects widely over each shoulder. It is thus with the war-jacket of some of the Dayak tribes, and was thus with the ceremonial *kamiscimo* of the Nippon *samurai*. The Nias shield, *balúse*, is peculiar, and made in a single board of tough light wood; in the northern parts of the island a heavier one, called *dagne*, more akin to Bornean and Celeban shields, is used. The characteristic weapons of the Niassers are the spear (*tòho*) and sword (*ballàtu*), the latter not unlike the Dayak *parang*. The iron spear-heads are generally small and narrow, simple, or more or less provided with barbs; the wood is from the Nibóng palm, and usually ornamented with rings of rotang, brass, or wire, and often with tufts of hair from an enemy's head. The sword is still more characteristic. Its sheath is made with two halves neatly fitted and bound together with plaited rotang; the big sword (*ballàtu sebúa*, "number one") is, especially in the south of Nias, the favourite weapon; much trouble is taken in ornamenting it, and the carved handle is often a remarkable specimen of wood-carving. Modigliani was fortunate enough to secure a series of these swords with carved handles, giving a most interesting instance of modification of a figure, in this case a boar's head, in the opposite directions of a simplified and a complicated conventionalism (Fig. 4). Moreover, the *ballàtu sebúa* of the Southern Niassers is

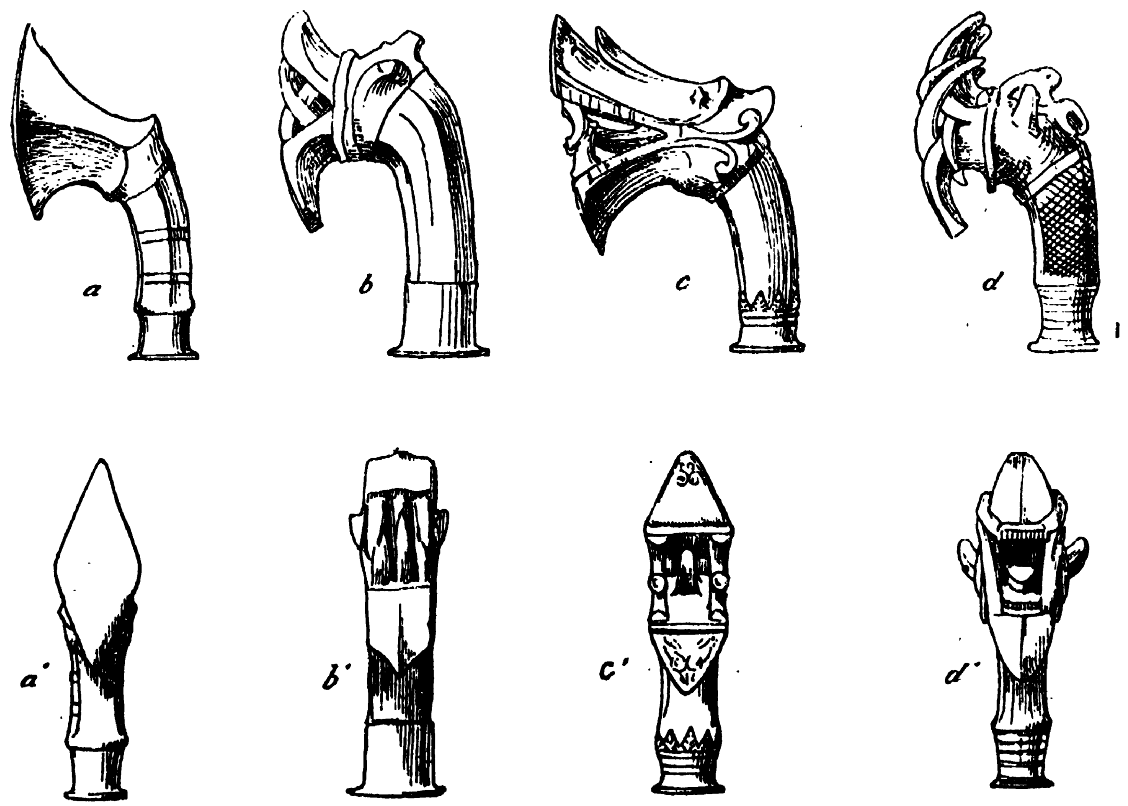

FIG. 4.—Carved sword-handles.

always provided with a singular appendage, with which the owner never parts willingly: it is an amulet and idol-bearer in the shape of a spherical basket of twisted rotang, with various and heterogeneous contents, such as teeth, pieces of stone and bone, &c., always several small idols roughly carved and anthropomorphous. All these are tied together and more or less wrapped up in a bit of cotton-cloth; their spherical hoeldr is securely fastened to the scabbard. Dr. Modigliani has given some highly interesting details on this subject; the *erè*, or "medicine

man," of the Niassers possesses a special talismanic sword with special idols and charms attached to the scabbard. Quite a number of old flint-lock muskets have found their way to Nias, but are fortunately often rendered useless from want of ammunition. The Niassers are able smiths, but they receive the iron and brass they use from Chinese and Malay traders.

On his way back, at Bàwo Lowaláni, Modigliani was able to buy from Faòsi Aro eleven human skulls. He next sailed to Luàha Gúndre Bay, wishing to visit the important village of Hili Sendrecheási, and possibly to proceed thence inland. He was well received by the chief and notabilities, who, however, promised much and did little. Another new bird was obtained here—*Terpsiphone insularis*, Salvad. Meanwhile, the head-man of another neighbouring village, Hili Simaetáno, sent messengers to invite him to go there, promising that he might stay and collect as much he liked. The death of a warrior at Sendrecheási gave Modigliani an opportunity of witnessing the funereal ceremonies of the Niassers, on which subject he gives much important information. He was not able, however, to confirm Piepers's assertion (*Bat. Genoot. v. Kuns. en Wettensch.*, 1887) regarding the horrid and singular custom of putting the body upright in a hollow tree, tapping this below, inserting a bamboo tube, and forcing a slave to drink the putrid liquid which flowed. The unfortunate man's head was afterwards cut off, and hung to the tree as an offering to him whose body was inclosed therein. I may mention that a similar custom is attributed to certain Dayak tribes of Borneo by Perelaer, and that it recalls the ancient Javanese *sétra*. It appears, however, that human lives are still sacrificed at the death of a chief. The author has also brought together highly interesting information as to "animism," belief in a future state, and ancestor-worship amongst the Niassers.

Although lamed, and suffering from a bad foot, he left Luàha Gúndre for Hili Simaetáno on June 1. His reception there was, however, the reverse of what he expected: the people were not only diffident, but evidently hostile, notwithstanding the invitation sent by their chief. Amongst the interesting things seen were two elaborately carved stone thrones of honour, used by the chief on solemn occasions; opposite one, on a pole, was a human skull. These two differed widely, the smaller one in the centre of the village being a sort of arm-chair, the back of which represented the bust of a warrior with a crocodile climbing up behind him. These singular stone seats of honour recall those found in far-off Ecuador. After a couple of days' stay, the hostility of the villagers was so evident that Modigliani decided to leave; and if he was not actually attacked, he owed it not only to his firmness and forbearance, but probably to the fear caused by his repeating-rifle, and to the villagers being short of ammunition. Anyway, he was able to get safely back to his *pencialàng*. Wishing, however, to penetrate into the interior of the island, he sailed to the Nácco Islands off the opposite coast of Nias, where he hoped to get guides and information. Mára Ali, chief of Nácco, received him well, and after much palavering and a liberal distribution of presents, he was able to obtain a guide in the person of Sanabahíli, brother of the local *erè*, and bearers. His intention was to land on the opposite coast of Nias, and penetrate inland to one of the higher mountains, known as Matgiúa, where he hoped to make interesting collections. Having landed, after a narrow escape from shipwreck, at Cape Scrombú, he proceeded boldly inland. There were no roads, and his progress was not easy or pleasant; moreover, his guide was hardly up to the office he had undertaken, and conducted him by mistake to the village of Idáno Dôwu. Thence he marched to Mount Buruássi, before reaching which most of his bearers had deserted; small villages were passed, and the sites of bigger ones which had been destroyed during the incessant wars. Halambáva, a strongly fortified village, was next visited; here he found a singular and grotesque idol, *Adú Fangúru*, carved in a cocoa-palm trunk on the occasion of an epidemic which had decimated the village. Crossing next the nearly unknown district of Iraòno-Una, peopled by ferocious head-hunters, he continued on to Hili Lowaláni; here he came to the conclusion that Mount Matgiúa had been purposely missed, or more probably was sadly out of place even in the best maps of Nias, and decided to return to the north. Travelling on by Hili Hôro, he came again to Hili Simaetáno, where he was well received this time, and able to buy some skulls. At the Luàha Gúndre he was rejoined by his *pencialàng*—not until after long waiting, anxious moments, and the risk of starvation, having finished his provisions—and sailed back to Gunong Sitoli. This voyage across the south-west end of Nias was an adventurous one, but hardly equal in results to the trouble it had cost.

After his return to Sitoli, Modigliani decided to spend what time he had left to remain in Nias in some favourable locality in the north, where, amongst quieter people, he might better complete his observations and collections. He selected the village Ombaláta, or rather the neighbouring hill called Hili Zabòbo; here he passed pleasant days and was able to do much. Amongst the interesting species collected I may mention: *Pteropus nicobaricus*, *Chiropodomys gliroides*, a rare and singular rodent lately collected by Fea in Burma; *Macropygia modiglianii*, Salvad., and *Carpophaga consobrina* Salvad., new pigeons; a rare and beautiful lizard, *Gonyocephalus grandis*, and the hitherto unknown *Aphaniotis acutirostris*, Modigl.; and several new species of Coleoptera and ants. It is worth notice that in more than 4000 specimens of Lepidoptera collected by Dr. Modigliani no novelties were found, but he secured some fine specimens of the rare and peculiar *Hebomoia vossi*, Maitl. Dr. Modigliani purposes publishing complete lists of the animals of Nias; meanwhile he has given in an appendix lists of the species he collected, having determined some himself, whilst others have been studied by several specialists. He obtained 15 species of mammals, 62 of birds, 39 of reptiles, 8 of batrachians, 71 of fishes, and lists of over 400 species of insects have already been published. The bulk of these zoological collections are in the Civic Museum of Genoa. Modigliani was not able to do as much in botany as he wished, but he was able to gratify Beccari with some choice specimens of his favourite *Myrmecodia* and *Hydnophytum*, those strange epiphytal ant-harbouring plants first noticed by Jack at Nias.

The last chapters of Dr. Modigliani's book are entirely devoted to the ethnology of Nias, and great and important is the amount of information which he has gathered on this interesting subject. I will merely mention one or two of the principal items. Discussing the origin and affinities of the Niassers, he finds them not only different from the ordinary Malay, but partaking of the characters of the Mongoloids (in a restricted sense) and even of the Arianoid races; and at the same time he notes physical differences between the natives of Northern and Southern Nias. I confess that I cannot quite follow our author in this: the Niassers most evidently belong to the great Malayan family, and perhaps resemble some of the Dayak tribes more than any others. The ancient and constant contact with Chinese may have slightly *mongolized* them, always in the more restricted sense of that term (some of Modigliani's photographs recalled to my mind portraits of Kwei-yings of North Formosa shown to me years ago by my lamented friend Robert Swinhoe). But I fail to see traces of Arianoid features in any of the Niassers photographed by Dr. Modigliani. At the same time, I can quite understand how he found points of resemblance between them and natives of Southern India, who evidently have Malayan blood in their veins.

Modigliani mentions seeing in South-West Nias natives with Arianoid Semitic features and curly or wavy hair, but he himself suspects in such cases the influence of Arabo-Malay immigrants from Acheen.

Amongst the many peculiarities of the inhabitants of Nias, is the custom of the women going about with a long slender stick called *sio;* it is of Nibong palm wood, has a heavy leaden knob, and is more or less ornamented with rings of lead and brass; it is found only in the possession of women. Great is the variety of ornaments worn by the Niassers, male and female. They often denote distinctions of rank and sex. Ear-rings and bracelets are especially varied; singularly beautiful are the bracelets (Fig. 5) carved and polished by a long and tedious process out of a solid block taken from the stony shell of the giant clam (*Tridacna*), more elegant in shape than the equally notable armlets of the same material made by the inhabitants of the Solomon Islands. The Niassers also carve big solid ear-drops out of the *Tridacna* shell. Their principal articles of dress are still made with the beaten and manipulated inner bark of a *Ficus* or *Arctocarpus*, a kind of *tappa* or *masi*, called by them *sambò salówo.*

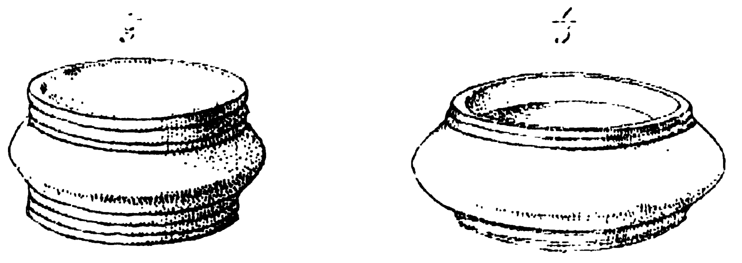

Fig. 5.—Bracelets cut in Tridacna shell.

Dr. Modigliani did not find or hear of stone or shell implements in Nias; possibly the first men who peopled that island were already provided with iron tools. Yet one of the commonest amongst these, the axe, *fáto*, has a singularly archaic form: the iron blade, very similar to the earlier forms of copper and bronze implements of the kind, is let into a slot in a short club-shaped wooden handle (Fig. 6). A yet more singular fact is that the *fáto* of the Niassers is a typical axe, and quite distinct from the adze used right across Malesia from the Nicobar Islands to New Guinea, being, instead, remarkably like the iron axe of some of the wilder tribes of Central Africa.

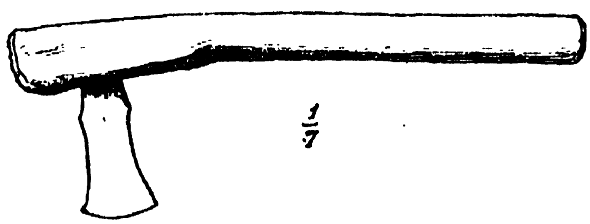

Fig. 6.—Iron axe o Nias

I may mention here that the rich and important anthropological and ethnological collections made at Nias by Dr. Modigliani have mostly been presented by him to the National Anthropological and Ethnological Museum in Florence.

Dr. Modigliani has collected quite a host of interesting facts relating to the myths and superstitions of the natives of Nias, which all appear to centre in a well-developed form of "ancestor worship." The ancestors more or less remote are spirits good and evil, and as mediators between them and the living are numerous *adú*, or idols (Fig. 7). Amongst the numerous spirits more or less divine venerated by the Niassers is *Sangaròfa*, the sea-god, and Modigliani justly calls attention to the strange similarity in name and attributes to *Tanga-roa*, the sea-god of the Maories and other Polynesians. The principal good spirit is *Lowaláni;* the bad ones are classified in two grades as *Bèchu'* and *Bèla*, these being, however, generic terms. The *adú* or idols, whose Nias name, by the way, is singularly like the equivalent Polynesian term *atua*, are very numerous; those which represent dead relations or immediate ancestors are called generically *Adú satúa.* They appear to have great affinities with similar carved wooden anthropomorphic figures common throughout Papuasia and Melanesia, and known as *karwars* in Western New Guinea.

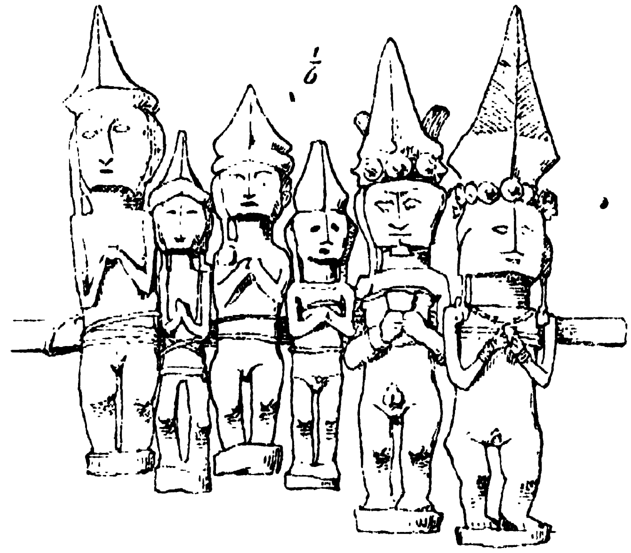

Fig. 7.—Images of ancestors.

In one of the last chapters of his book, Modigliani gives an account of the spoken language of the Niassers, which has many peculiarities; adding an alphabetically arranged collection of words with their Italian equivalents.

But my task, which has been to endeavour to give an idea of the work done by Dr. Modigliani, must now come to an end. His book, containing a very complete monographic study of one of the most interesting islands of the Indian Archipelago and its inhabitants, is, and will long remain, one of the standard works on that beautiful region Malesia. HENRY H. GIGLIOLI.

NOTES.

THE next general meeting of the Institution of Mechanical Engineers will be held on Thursday evening, May 1, and Friday evening, May 2, at 25 Great George Street, Westminster. The chair will be taken at half-past seven on each evening by the President, Mr. Joseph Tomlinson. On Thursday evening the President will deliver his inaugural address, after which the following paper will be read and discussed, and the discussion will be continued on Friday evening:—Research Committee on Marine-Engine Trials: Report upon Trials of three Steamers, *Fusi Yama*, *Colchester*, *Tartar*, by Prof. Alexander B. W. Kennedy, F.R.S., Chairman. The anniversary dinner will take place on Wednesday evening, April 30.

THE first annual meeting of the Museums' Association will be held in Liverpool on June 17, 18, and 19. The business of the meeting will consist of (1) the reading of papers on the management, arrangement, and working of Museums; (2) the discussion of the objects set forth by the meeting of June 20, 1889, with special reference to the following points: the means of interchange of duplicates and surplus specimens; schemes for a general supply of labels, illustrations, &c.; the indexing of the general contents of Museums; concerted action for obtaining Government publications, and also specimens on loan or otherwise; and the issue of a journal devoted to the discussion of practical topics. At this meeting the scheme for the constitution of the Association will be submitted. All engaged or interested

in Museum work are cordially invited to join the Association. The conditions of membership are as follows:—Each Museum contributing not less than one guinea a year becomes a member of the Association, and can send three representatives to the meetings. Individuals interested in scientific work are admitted as Associates on payment of 10*s.* 6*d.* annually. The following are the officers of the Association:—President: Rev. H. H. Higgins; General Secretaries: H. M. Platnauer, Museum, York, T. J. Moore, Museum, Liverpool; Local Secretaries: R. Paden, Museum, Liverpool, H. A. Tobias, Museum, Liverpool.

THE next *conversazione* of the Royal Microscopical Society will be held on Wednesday, the 30th inst., at eight o'clock.

HERR O. JESSE sends us from Steglitz, near Berlin, some very beautiful photographs of luminous night clouds. The photographs of each pair were taken simultaneously at Nanen and Steglitz. Steglitz lies 8 kilometres south-west, Nanen 38 kilometres west-north-west, of the Berlin Observatory. Herr Jesse would add greatly to the value of his work if, the next time he has an opportunity of undertaking it, he would photograph the spectrum.

La Nature (April 12, p. 303) notes the following curious and interesting phenomena:—Two railways, one the Sceaux line and the other the Ceinture, pass within a comparatively short distance of the Montsouris Observatory, Paris, the former line being about 80 metres distant, and the latter but some 60 metres. During the passage of trains on the Ceinture line, which is nearest to the Observatory, the bifilar magnet is found to be disturbed, and its oscillations are registered photographically; indeed the movements are so regular that the curve clearly indicates the exact time of each train passing the Observatory. This phenomenon is due to the fact that as the line crosses the direction of the magnetic meridian the wheel-tires of the carriages become magnetized by induction, and so produce, in consequence of the laws of magnetism, a deviation of the bifilar magnet. The trains on the Sceaux line give rise to a phenomenon not less curious. Whenever the engine-driver blows off steam, the electrometer is partly discharged, the electrical potential of the air falling to about one-half of its original value. These disturbances are brought forward by the Director of the Paris Observatory in order to oppose the scheme which is now proposed of extending the railway from Sceaux to la Place de Médicis.

ON Tuesday evening, M. Jacques Bertillon (head of the Municipal Bureau of Statistics in Paris) delivered a lecture before the Anthropological Institute of Great Britain and Ireland, on the method now practised in France of identifying criminals by comparing their measures with those of convicted persons in the prison registers. Mr. Bertillon, who spoke in French, said that the system which he had come there to explain had for its object the recognition of a person 10, 15, 20, or even 100 years after he had been measured, for by that method it was possible to recognize a person after death, if access could be had to his skeleton. Photography was now used only as an aid to identification established by other means. The basis of the anthropometic system was to obtain measurements of those bony parts of the body which underwent little or no change after maturity, and could be measured with extreme accuracy to within so small a figure as to be practically exact. These parts were the head, the foot, the middle finger, and the extended forearm from the elbow. To clearly illustrate the system, let them suppose 90,000 photographs of men to have been collected. These would be divided into three groups of 30,000, according to the height of the men. There would be short men, men of medium height, and tall men. That these three classes might be approximately equal, it was evident that the limits of the class of men of medium height must be restricted more than those of the other two classes. Each of these primary divisions should again be divided on the same principle, without taking any further notice of the height, into three classes, according to the length of the head of each individual. The three classes of short, medium, and long heads would each again be subdivided into three, according to the width of the heads, and would contain narrow, medium, and wide heads. Experience had proved that with most people the breadth of the head varied independently of the length—that was, given that an individual had a certain length of head, it by no means followed that the breadth of his head could be determined *a priori*. The length of the middle finger gave a fourth and still more precise indication by which to divide again each one of the packets of photographs; and these might be divided again according to the length of the foot, the length of the arms outstretched at right angles to the body, and also according to the colour of the eyes. Thus by these anthropometrical coefficients they would be able to divide their collection of 90,000 photographs into very small groups of about 15 each, which they could easily and rapidly examine. M. Bertillon then proceeded to give a practical demonstration of the way in which the measurements were taken. He laid stress on the importance of the hand and the ear as marks of cogniti on. The hand, because it was the organ in most constant use in almost every calling and in many trades and professions, became modified according to the particular character of the work which it had to do. The ear was the precise opposite to this. It changed very slightly, if at all, except perhaps in the case of prize-fighters, who developed a peculiarity of the ear which it was easy to recognize. The ear, therefore, was an important organ to measure, inasmuch as the results were not likely to be nullified by a change in its conformation.

THE following telegram was sent through Reuter's agency from New York on April 21:—"Despatches from Mexico state that observations show that the height of the active volcano of Popocatepetl has decreased by 3000 feet since the last measurement was taken."

IN the new quarterly statement of the Palestine Exploration Fund, the Committee announce that they have obtained a firman granting permission to excavate at Khürbet 'Ajlân, the Eglon of Joshua. It is understood that all objects, except duplicates, found in the course of the excavations shall be forwarded to the Museum at Constantinople, but that the Committee's agents shall have the right of making squeezes, sketches, models, photographs, and copies of all such objects. The Committee have been so fortunate as to secure the services of Mr. Flinders Petrie, who is now in Syria making arrangements to start the excavations.

THE death of Dr. Gottlob Friederich H. Küchenmeister is announced. He was a great authority on Entozoa.

IN the official outline of the principal arrangements at the Crystal Palace for the summer of 1890, reference is made to the International Exhibition of Mining and Metallurgy which is to be held there from July 2 to September 30. The subjects embraced within the scope of the Exhibition comprise machinery in motion and at rest; gold, silver, diamond, iron stone, and iron ore mining; manufacture of iron and steel; lead mining and manufacture; tin mining and smelting; copper and coal mining; the petroleum and salt industries; mining for precious stones, &c. There is every reason to expect, through the co-operation of colonial and foreign Governments, many valuable exhibits from abroad.

THE *Engineer* and *Engineering* of last week publish long illustrated accounts of the recent disaster to the City of Paris

This accident is without a parallel in the history of steam navigation; the circumstances were so remarkable that many conflicting explanations of the cause have been suggested. The ship is propelled by twin screws, and the engines are placed side by side in separate compartments. When she was off the coast of Ireland, at half-past five on the evening of the 25th ult., the low-pressure cylinder, with the whole of its gear, of the starboard engine, went to pieces, and fell to the bottom of the engine-room in a confused mass, the *débris* of the top cylinder cover being apparently at the bottom of the wreck. The smashing of the condenser allowed an enormous rush of water to flood the starboard engine-room, and the longitudinal bulkhead between the engines, being also damaged, allowed the port engine-room to become flooded, and of course stopped that engine from working. Our contemporaries say that, in the opinion of experts in Liverpool, the accident did not originate in the engine, but in the tail shaft, as follows: the brass liner on the tail shaft burst; then the lignum-vitæ strips were torn out, bringing metal to metal. This, naturally, would allow the steel shaft to grind itself and the bracket away, and the shaft dropped. Then the continual bending of the shaft resulted in its fracture. The engines, being relieved of the resistance of the screw, raced, with the result shown in the engravings. The *Engineer* at present neither accepts nor rejects this theory of the cause of the disaster.

THE Manchester Field Naturalists' Society opened the summer excursion session on the 19th inst., by a visit to the well-known herbaceous garden of Mr. Wm. Brockbank, Withington, near Manchester. The grounds, of about six acres in extent, are laid out in woodland, shrubbery, rockeries, and fernery, with a patch of wilderness, and are entirely devoted to the growth of the native flowers, and the horticulturists' modifications, so far as they will thrive. The special feature, at the time of the visit, was the display of daffodils, over a hundred varieties being included in the gardens, several of them locally raised. Mr. Brockbank explained that the double variety of the daffodil is not obtained by the absorption of the essential organs, as generally supposed; the pistils and stamens remain, and specimens were shown, in vigorous health, obtained from their seeds.

IT has been suggested that the epidemic of influenza was in the last resort due to floods in China. The fertile land in the valley of the Yellow River, it has been said, was covered with a deposit of alluvial mud, and in this mud countless numbers of organic spores were developed from the refuse of a dense population. These germs were carried by merchandise to Russia, whence they spread to Europe generally. Dealing with this theory, the *Shanghai Mercury* points out (1) that there has been no epidemic of influenza in China. (2) There is no valley whatever of the Yellow River, the peculiarity of that stream being that it flows on the surface of the ground, which actually slopes down on both sides from the river bed, so that in case of a breach of either embankment the river is free to flow to the sea almost anywhere between Tientsin in the north, and Shanghai in the south. (3) The plain of the Yellow River is by no means fertile, and is rapidly deteriorating. (4) So far from the deposit left after a breach being alluvial mud, it is unmitigated sand, and for years refuses to grow any crops whatever; and it is only after an exposure of some fifteen or twenty years that the phosphates which enter sparingly into its composition begin to break up, and the land is restored to cultivation. (5) There are no exports of any sort from the plain of the lower Yellow River. Almost the only product exported to Europe from districts anywhere near the river is straw braid, which is shipped not to Russia but to England and the United States; and this not from the plain, but from the highlands of Shantung, far removed from any communication with the river.

THE Ballarat School of Mines, in the University of Melbourne, presented its annual report at a meeting of governors and subscribers on Monday, January 20. The general efficiency and usefulness of the school have been greatly promoted by extensive additions to the buildings and plant, and the numerous improvements effected in connection with the mining and metallurgical departments. That the institution now affords a superior training in scientific and mining subjects is shown by the attendance of a more advanced class of students, and by the better results obtained at the examinations. It attracts to its classes students from all the neighbouring colonies, including Queensland, New South Wales, South Australia, and Tasmania, as well as from distant places within Victoria. The total number of enrolments in the various classes held during the year was 982, and of individual pupils who attended the elementary science lectures delivered in the State schools, 723. The mean average number of students in attendance at the school classes for the whole year was 526, whilst during the same period 286 lectures on elementary chemistry were delivered in nine of the State schools in the city and town, with an average attendance of 53 at each lecture.

MR. A. J. CAMPBELL has returned to Melbourne after a three months' trip in Western Australia. The *Victorian Naturalist* says he has been very successful in his observations and collections. He obtained about 80 different species of eggs, 13 of which it will be necessary to describe as new. The number of eggs obtained altogether was about 400. About 100 skins of birds were collected, though Mr. Campbell made no special effort to secure them. With regard to geographical range of birds he was particularly successful in his observations. No less than 17 species will be recorded as new for Western Australia. Possibly one or two may be deemed new varieties, while others will be restored, having been omitted from a lately issued tabular list. Baron von Mueller has examined the plants, and finds that two ferns, *Asplenium marinum* and *A. trichomanes* (both British species, by the way) are recorded for the first time from the western colony. Of 30 lichens collected, the Rev. F. R. M. Wilson has identified 20 as new for the same colony. Specimens of characteristic lizards and frogs (*e.g.*, *Heleioporus albo-punctatus*) were secured. About three dozen photographs turned out fairly well, those of the remarkable flights of sea-birds being of great interest. Mr. Campbell considers that he brought nearly 1000 natural history specimens back to Melbourne.

IN the latest of his series of instances—printed in the *American Naturalist*—of the effect of musical sounds upon animals, Mr. R. E. C. Stearns mentions the case of a canary "who is particularly fond of music." This interesting bird belongs to the Rev. Mr. James, who writes as follows:—"Immediately I begin to play upon the flute she chirps about as if enjoying the music. If I open the cage-door and leave her, she will come as near to me as possible, but not attempt to fly to the music; but if I put her upon my desk, and lay the flute down, she will perch upon the end, and allow me to raise the instrument and play. I often take her into the church and play there upon the organ, and she will perch upon my fingers, notwithstanding the inconvenience of the motion of the hands, and chirp in evident delight at the sweet sounds."

LAST week Prof. Stricker submitted to the International Medical Congress at Vienna a new electrical lantern which will, it is expected, be of great service to lecturers and medical students. According to the Vienna correspondent of the *Times*, Prof. Stricker, by an ingenious combination of lenses, contrives to project the magnified images of objects on a white screen in their natural colours, so that, for instance, a small pimple on a patient can be shown in its real appearance to an audience of many hundred students.

At the seventh Congress of the American Ornithologists' Union, Dr. R. W. Shufeldt read a report on progress in avian anatomy for the years 1888–89. Towards the end of this report, which has now been reprinted separately, Dr. Shufeldt said he had greatly felt the need of a good hand-book to the muscles of birds. In looking about him, he soon found that there was no such manual in the English language; at least, there was not the kind of work that the thorough dissector required. To meet this want he undertook the preparation of a volume devoted to the subject. A thoroughly cosmopolitan form, or rather a form well representing a cosmopolitan group of birds, the raven, was selected. He carefully dissected out on many specimens every muscle of this type, and figured them in a careful series of drawings. These he supplemented by a series of drawings of the skeleton of the same form, and on the bones indicated the origin and insertion of all the muscles. Full descriptions were written out, and the groups of muscles classified; and finally some comparative work was added. Both the drawings of the muscular system, as well as the skeleton, were life-size, which made the parts very clear and convenient for use. "To my surprise," says Dr. Shufeldt, "when it was all completed, the manuscripts for a small volume were on my hands." The work is now in the press, and will be published shortly by Messrs. Macmillan and Co.

Two volumes of the *Internationales Archiv für Ethnographie* have now been completed. With the current number, just issued, the third volume begins. In a prefatory note, the editor, Dr. Schmeltz, refers with satisfaction to the help he has received from eminent contributors; and he is able to promise that the periodical shall be not less instructive and interesting in the future than it has been in the past. In the present number there are several valuable papers. One of them, by Dr. Franz Boas, deals with the use of masks and head-ornaments on the north-west coast of America. Herr Strebel, of Hamburg, contributes the first of a series of "studies" on a peculiar kind of stone implements found in Mexico and Central America. Hitherto it has been generally supposed that these implements were put on the necks of human victims destined for sacrifice. The author undertakes to show that this view is mistaken.

The Journal of the Anthropological Institute (vol. xix. No. 3) contains an elaborate and most interesting paper, by Prof. A. C. Haddon, on the ethnography of the western tribe of Torres Strait. The other contributors to this number are Dr. Beddoe, who writes on the natural colour of the skin in certain Oriental races; and the Rev. James Macdonald, who has a paper on the manners, customs, superstitions, and religions of South African tribes.

The *Photographic Quarterly*, of which three numbers have been published, meets a need which must often have been felt by those who specially devote themselves to photography. It includes among its contributors many eminent students, and deals freely with all important questions in which photographers are interested. The third number opens with an article on photography of the sky at night, by Captain W. de W. Abney. Among the other contents are papers on the limits and possibilities of art photography, by George Davison; photogravure and heliogravure, by P. G. Hamerton; the optical lantern as an aid in teaching, by C. H. Bothamley; and a phase of naturalistic focussing, by H. Dennis Taylor.

A complete index of the papers printed in the Proceedings of the London Mathematical Society has been issued. It will be of great service to all who have occasion to refer to the series, which now includes twenty volumes.

A catalogue of the books in the library of the Indian Museum has been issued by the trustees. It has been compiled by Mr. R. Leonard Chapman. The number of separate works in the library is about 3500, and every facility is given to students consulting them. In a prefatory note Mr. J. Wood-Mason, superintendent of the Indian Museum, says that most of the books are on zoology and kindred subjects, and he has no doubt that "the gradual spread of scientific education in India will largely extend the field of usefulness of the Museum library in the future."

A new acid, , the first member of a series possessing the generic formula $C_nH_{2n-2}O_2$, derived from the saturated hexa-hydride of benzene,  the so-called naphthene and its homologues of the generic formula C_nH_{2n}, has been isolated by Dr. Ossian Aschan, of the University of Helsingfors, from the natural oil of Baku (*Berichte*, 1890, No. 6, p. 867). The acid may be considered as a saturated hexahydride of benzoic acid; it is a very stable liquid substance of strongly acid properties, readily decomposing calcium chloride with evolution of hydrochloric acid and formation of a calcium salt. The raw mixture of acids obtained by treating the oil with alkali, and subsequent decomposition of the sodium salts by dilute sulphuric acid, was first distilled and the lower boiling portion specially examined. Upon partially saturating this fraction with caustic soda solution, and again decomposing with sulphuric acid, a colourless oil separated. In order to separate the various acids contained in this oil, they were converted into methyl esters by the action of methyl alcohol and strong sulphuric acid. These esters were then submitted to fractional distillation, when a large quantity of an ester boiling constantly at 165°·5–167°·5 C. was eventually isolated, possessing the composition $C_6H_{11}.COOCH_3$. This was, in fact, the methyl ester of the new acid, the first member of the series, of which other higher members have previously been obtained by Markovnikoff and others. The methyl ester is a highly refractive colourless oil of pleasant fruit-like odour. By saponification with alcoholic potash, crystals of the potassium salt of the acid itself were obtained. On acidification of the aqueous solution of these crystals, the free acid separates as an oil, which after rectification boils constantly at 215°–217°. It is a colourless thick liquid of unpleasant and very persistent odour, and does not solidify at − 10°. Its strength as an acid has already been alluded to as evidenced by the turning out of hydrochloric acid from chlorides of the alkaline earths; moreover, the calcium and barium salts are not decomposed by carbonic acid. Strong sulphuric acid readily dissolves it, with decomposition upon heating. Its specific gravity at 18°·4 is 0·95025. This acid is isomeric with the methyl pentamethylenic acid synthesized by Messrs. W. H. Perkin, Jun., and Colman, the latter boiling a little higher, at [illegible]–219°·5 and possessing a higher specific gravity, 1·02054 at 15°. The potassium salt $C_6H_{11}COOK$ is a soft soap-like substance, which may sometimes be obtained in distinct crystals. It is readily soluble in water and alcohol and is strongly hygroscopic. The sodium salt much resembles its potassium analogue, and may be obtained crystallized in flat prisms from alcohol. It likewise deliquesces very rapidly in the air. The calcium salt dissolves readily in alcohol, but is more difficultly soluble in water. If an aqueous solution is allowed to evaporate over oil of vitriol, the salt, $(C_6H_{11}COO)_2Ca + {}_4H_2O$, is obtained in long needles. If a solution saturated at the ordinary temperature is heated to boiling, it becomes turbid and viscous drops begin to separate; these

again dissolve on cooling. This behaviour is very characteristic of the acid, the barium salt showing the phenomenon also in a striking manner. It is due to the different amounts of water of crystallization in the salts separating at different temperatures. The chloride of the acid radical, the amide, and the anilide of the acid have also been prepared, and found to resemble the corresponding derivatives of the fatty acids.

THE additions to the Zoological Society's Gardens during the past week include two Indranee Owls (*Syrnium indranee*) from Ceylon, presented by Mr. A. R. Lewis; two Lataste's Frogs (*Rana latasti*) from Italy, presented by Mr. G. A. Boulenger, F.Z.S.; a Common Moorhen (*Gallinula chloropus*), British, two Moorish Toads (*Bufo mauritanica*) from North Africa, presented by Mr. Cuthbert Johnson; an Indian White Crane (*Grus leucogeranos*), two Black-gorgeted Jay Thrushes (*Garrulax pectoralis*), an Indian Muntjac (*Cervulus muntjac* ♂) from India, deposited; a Pacific Fruit Pigeon (*Carpophaga pacifica*) from the Solomon Islands, four Madagascar Weaver Birds (*Foudia madagascariensis*, 2 ♂ 2 ♀) from Madagascar, six Common Cormorants (*Phalacrocorax carbo*), European, two Adelaide Parrakeets (*Platycercus adelaidæ*) from South Australia, purchased; a Puma (*Felis concolor*), born in the Gardens.

Remarks.

(1, 2, 3) Although the constellation Virgo is so exceptionally rich in nebulæ, comparatively few of them have been submitted to spectroscopic examination. Smyth remarks that "the situation of the extraordinary conglomerate of nebulæ and compressed spherical clusters which crowd the Virgin's left wing and shoulder is pretty well pointed out to the practised naked eye by ε, δ, γ, η, and β Virginis, forming a semicircle to the east, whilst, due north of the last-mentioned star, β Leonis marks the north-west boundary." As it is not possible to give anything like a complete list, three of the brighter ones which have not yet been spectroscopically observed have been selected. No. 1 is the remarkable spiral nebula 99 M Virginis, and is thus described in the General Catalogue:—"A very remarkable object; bright; large; round; gradually brighter in the middle; three-branched spiral." No. 2 is 87 M Virginis, and is described as "Very bright; very large; round; much brighter in the middle." No. 3 is described as "Very bright; considerably large; pretty much elongated in a direction about 63°; very suddenly much brighter in the middle to a nucleus." It is a remarkable fact that all the nebulæ in Virgo, which have so far been examined, exhibit so-called "continuous" spectra. D'Arrest observed the nebulæ G.C. 2930 (84 M Virginis), 2961 (86 M), 3021 (49 M), and Lieutenant Herschel observed G.C. 3021, 3132, 3227, 3229, and 3397. Some of these may be re-examined for bright maxima in the continuous spectra.

(4) The spectrum of this (Group II.) star is thus described by Dunér:—"The bands 2-8 are well marked by strong lines which terminate them on the violet sides. But, with the exception of 2 and 3, they are rather narrow, and the spectrum approaches to the type of Aldebaran." The star is obviously at a transition stage between Groups II. and III., and a special detailed study of the lines and bands should be made.

(5, 6) The spectra of these two stars have been observed by Vogel, who states that the first has a spectrum of the solar type, whilst the second is one of Group IV. The usual further observations are required in each case.

(7) Notwithstanding the small magnitude of this star, it has, according to Vogel, a magnificent spectrum of Group VI. The star is not included in Dunér's Catalogue, and Vogel gives no particulars as to the number and character of the bands present. Further detailed observations are obviously required. The intensity of the carbon band near λ564, as compared with the other bands, should be particularly noted.

(8) This variable will reach a maximum about April 27. Its period is about 225 days, and it varies from 7·2–8·2 at maximum to 10·2–12·8 at minimum. According to Dunér, the spectrum is one of Group II., but very feebly developed. As no details of the spectrum are given, it seems probable that the observation was made near minimum, and the present maximum may afford an opportunity of securing further observations. As in similar variables, bright lines may also be looked for.

A. FOWLER.

MATHEMATICAL STUDY OF THE SOLAR CORONA.—The Smithsonian Institution, Washington, has published a paper by Prof. Frank H. Bigelow in which the solar corona is discussed by spherical harmonics. The subject is treated by this theory on the supposition that the phenomenon seen is similar to that of free eleectricity, the rays being lines of force and the coronal matter being discharged from the body of the sun, or arranged and controlled by these forces. In order to give the solution a general foundation the important parts of the theory of harmonics specially relating to the case are recapitulated, and the corresponding geometrical solution given in a notation adapted to the sun. An analysis of the lines of force demonstrates the applicability of the formulæ of statical electricity to the coronal structure, hence some repulsive force must exist on the surface of the sun which acts upon the corona according to the laws of electric potential. It is shown how the concentration of potential at each pole throws vertical lines of force at the polar region, which gradually bend each side, and finally close on the equator at a certain distance from the centre. Similarly other lines are traced which leave the sphere at various angles to the vertical axis and have diminished potentials; these therefore close on the equator at a less distance from the centre than the high potential vertical lines thrown out at the polar region.

Applying these electrical principles to the solar corona, the author thinks that the straight polar rays of high tension carry the lightest substances, such as hydrogen, meteoritic matter, *débris* of comets and other coronal material away from the sun, and they soon become invisible by dispersion. The strong quadrilateral rays which form the appendages conspicuously seen at periods of great solar activity are produced by four lines of force having potential 0·9, 0·8, 0·7, and 0·6, of the potential at each pole, and the explanation of the long equatorial wings, with absence of well-marked quadrilaterals, seen at periods of minimum, is that they are due to the closing of the lines of force about the equator. The theory is tested by applying it to two photographs taken by Messrs. Barnard and Pickering on January 1, 1889, and Prof. Langley submits it to astronomers and physicists as a possible clue to the explanation of the corona and as suggesting the direction to be taken in future observations and investigations.

SOLAR OBSERVATIONS.—The following is the *résumé* of solar observations made at Rome, by Prof. Tacchini, during the first three months of this year:—

Spots and Faculæ.

ASTRONOMICAL SOCIETY OF FRANCE.—The following officers have been elected for the session 1890-91:—President, M. H. Faye, Member of the Institute. Vice-Presidents: MM. Bouquet de la Grye, Member of the Institute; Camille Flammarion, Laussedat, and Trouvelot, of Meudon Observatory. Secretaries: MM. Ph. Gérigny, Armelin, and Bertaux.

The Society meets at the Hôtel des Sociétés Savants, 28 Rue Serpente, Paris, and there is an Observatory and a Library open to the members.

D'ARREST'S COMET.—The following ephemeris for the search for this periodic comet on its return this year is given by M. G. Leveau in *Astr. Nach.*, No. 2959:—

Ephemeris for Paris Mean Time.

INFLUENZA AND WEATHER, WITH SPECIAL REFERENCE TO THE RECENT EPIDEMIC.[1]

IN this inquiry the authors deal only with deaths recorded by the Registrar-General as due to, or caused by, influenza in London between the years 1845-90. The statistics for London are selected because there is there a vast population in a small area, all subject to the same climatic conditions, and because there is also there a weekly record of deaths and their causes for a long period, which they discussed with some fulness of detail some years ago.

After making allowance for certain errors to which such an inquiry is liable, arising chiefly from the methods of registration, it is found that the figures recorded disclose certain phenomena with such emphasis that the lessons taught by the phenomena stand altogether unaffected. Thus, as regards the distribution of deaths over the year, during the 45 years, the results show a strongly marked winter maximum and an equally marked summer minimum; along with which there is also a small secondary maximum in the second half of March and first half of April. Thus, broadly considered, the distribution of deaths from influenza is inversely as the temperature, being at the maximum during the winter months when temperature is lowest, and at the minimum in the summer months when temperature is highest. Hence the curve showing the distribution of deaths from influenza is closely congruent with the curve for diseases of the respiratory organs, with the addition of a slight rise in spring, thus suggesting a connection between influenza and diseases of the brain and the nervous system.

During the last 45 years, 4690 deaths are registered as having occurred from influenza, or 104 per annum. There is no year in which there has not been some deaths recorded as due to influenza; but during the 12 years ending with 1889, the registered deaths have been decidedly fewer than during the preceding 33 years, the mean number for these 12 years being only 6⅓, falling in some of the years as low as 3. There have been five periods during these years in which the figures point to the prevalence of an epidemic of influenza, the exact periods of which, with the number of deaths registered as due to influenza, are these:—

	Deaths.
December 1847 to April 1848	1631
March to May 1851	258
January to March 1855	130
November 1857 to January 1858	123
January to March 1890	545
Total	2687

Thus the five epidemics yielded 2687 of the 4690 deaths registered, or about 57 per cent. From a discussion of the details of each epidemic and the weather which prevailed during each of them, it was shown that in each case the rise to the maximum was strikingly rapid after the disease was recognized as existing. It was further concluded that the epidemics of influenza in this country were not, though they occurred during the winter, connected with exceptionally cold weather, especially at their commencement, but on the contrary rather with exceptionally warm weather, which manifested itself generally both before and during the epidemic. In no case that has occurred was any exceptionally cold weather intercalated in the period of the epidemic, accompanied with an increase of deaths from influenza, or even with an arresting of the downward course of the curve of mortality, if the cold occurred at the time the epidemic was on the wane. This fact presents influenza under widely different relations to temperature as compared with all diseases of the respiratory organs.

During the first four weeks of 1890, when the mortality from influenza was at the maximum, the total mortality from all causes was 2258 above the average of these weeks, and of this number influenza only accounted for 303, thus leaving 1955 deaths due to other causes; and it is here to be noted that during the time there were no weather conditions, such as excessively low temperature or dense persistent fogs, which could account for this very large increase of the death-rate. It thus became a point of interest to ascertain what the diseases were which had an exceptionally high mortality during the period, and on the other hand whether there had been any diseases with a mortality for the time much under the average.

The statistics from the various diseases were minutely examined, from which it was shown that those which yielded an exceptionally high death-rate during the influenza epidemic were diseases of the respiratory organs, phthisis, diseases of the circulatory system, rheumatism, and diseases of the nervous system. These diseases, particularly those of the respiratory organs, produced a very large excess above their averages, in spite of the fact that on the whole temperature had been particularly high, and dense fogs absent, which, being contrary to all rule, plainly indicated that during the period something of an exceptional character had been operating to increase the deaths from diseases of the respiratory organs. The strong manifestation of nervous symptoms in the severe headaches and prostration which attended the attacks of influenza, make the increase of deaths from diseases of the nervous system and of phthisis deeply interesting, as suggestive of a relation to the secondary spring maximum. So, also, the increased number of deaths from rheumatism is interesting in connection with the muscular pains which were so constant a symptom of influenza.

The diseases which yielded a mortality under the average during the prevalence of the epidemic were diarrhœa and dysentery, liver disease, measles, scarlet fever, typhoid fever, and erysipelas. It is, however, necessary to remark that the figures refer only to London, and that in other places where epidemics of measles and scarlet fever prevailed at the time these epidemics might show a mortality above the average.

On the question of age, the point of interest centred in the fact that the death-rate of all persons above the age of 20 rose considerably above the average during the four or five weeks immediately preceding the commencement of the registration of deaths due to the epidemic. Thus, though deaths from influenza were not registered in November and December, there appeared to have been something then present, apart from weather, which increased the mortality of all persons above the age of 20 much above the mean. At ages under 20 years, the death-rate rose above the mean only in the first three weeks of the year.

From a list of twenty-three recorded epidemics of influenza since the year 1510, it appeared that spring epidemics were more frequent and better marked than they would be if the figures for the past forty-five years were accepted as revealing the whole truth; and it also appeared that the epidemic of influenza has occurred in early summer and continued to the end of July. Facts, however, are too scanty to show whether the increased mortality during this early summer epidemic extended to the classes of diseases which have their annual maximum mortality in early summer, in a manner similar to the greatly increased mortality from diseases of the respiratory organs or of the nervous system according as the epidemic falls during the winter or the spring months.

In conclusion it was remarked that in discussions regarding

[1] Abstract of a Paper, by Sir Arthur Mitchell and Dr. Buchan, read at the half-yearly meeting of the Scottish Meteorological Society, March 31, 1890.

the spread of the germs of diseases from one country to another by the intervention of winds, it had been perhaps universally assumed that it is only the winds blowing over or near the surface of the earth which were concerned in the dissemination of these germs. Generally it has been concluded that, if the surface winds do not account for the successive appearances of the epidemic at different points, the germs have not been transported by the winds. This, however, is only a mode of looking at the subject which ignores the recent developments of meteorology and its teachings regarding atmospheric circulation through cyclones and anticyclones. As is now virtually proved, the winds in a cyclone are drawn inwards towards its centre, and thence ascend in a vast aërial column to the upper regions of the atmosphere, whence again they flow as an upper current towards any anticyclone or anticyclones that may be in the surrounding region. Thereafter they slowly descend down the centre of the anticyclone to the earth's surface, over which they are carried in every direction. Thus, for example, from a cyclone in Russia, a vast column of air rises from the surface, carrying with it particles of dust, germs, and other light impurities. These are then conveyed by the upper current to the anticyclone that may at the time overspread Western Europe, and thereafter descend to the surface, and are then distributed over Western and Central Europe by winds from all points of the compass. Owing to the rapidity of these aërial movements, two or at most three days are amply sufficient for this distribution.

MATHEMATICAL TEACHING AT THE SORBONNE, 1809–1889.

THE following brief sketch of the illustrious Professors who have during the last eighty years occupied the mathematical chairs at the Sorbonne is founded upon an interesting address by the veteran mathematician, M. Ch. Hermite.[1]

The occupants, in 1809, of the respective chairs, were Lacroix (Differential and Integral Calculus), Poisson (Mechanics), Biot (Astronomy), Francœur (the Higher Algebra), and Hachette (Descriptive Geometry). Each, in his respective department, has left traces of his power which are still in evidence. "Nous évoquons le souvenir de ces hommes éminents qui ont honoré la Faculté des Sciences à son origine; nous voulons rendre l'hommage qui est dû à leur mémoire, et dans cette circonstance rappeler leurs titres à la reconnaissance du pays." M. Hermite then proceeds to analyze in turn the work of the above Professors.

(1) Of Lacroix, he says: "La constante préoccupation de l'auteur a été d'établir entre tant de théories qu'il expose, sur des matières si diverses, une succession naturelle, un enchaînement qui en facilite l'étude et contribue à l'intelligence générale de l'analyse." He was well followed by Lefébure de Fourcy.

(2) Francœur occupied his chair down to 1847; he was the author of a long list of works. "La concision que s'est imposée l'auteur pour réunir tant de matières dans un court espace ne porte jamais atteinte à la clarté." A sketch of the "Uranographie" is furnished by M. Tisserand.

(3) Biot was also a long occupant of his chair, "dont il est resté titulaire jusqu'en 1846." M. Wolf furnishes a note (pp. 36–40) which gives a full account of the "Traité Élémentaire d'Astronomie physique." "Biot était un érudit et un écrivain," in M. Hermite's judgment.

(4) Poisson is a Colossus:—"Il figure parmi eux à côté de Laplace, de Lagrange, et de Fourier. C'est surtout de l'auteur de la 'Mécanique Céleste' qu'il se rapproche par la nature de ses travaux, son génie analytique, sa puissance pour mettre en œuvre toutes les ressources du calcul. Lagrange, à qui l'on doit la 'Mécanique Analytique,' et de grandes découvertes dans la théorie du son et la mécanique céleste, avait consacré une part importante de ses efforts aux mathématiques abstraites; après avoir fondé le calcul des variations, il a laissé la trace de son génie dans l'algèbre et la théorie des nombres. Pour Laplace et Poisson, l'analyse pure n'est point le but, mais l'instrument; les applications aux phénomènes physiques sont leur objet essentiel, et Fourier, en annonçant à l'Académie des Sciences les travaux de Jacobi, a exprimé le sentiment qui dominait à son époque, dans ces termes que nous reproduisons: 'Les questions de la philosophie naturelle qui ont pour but l'étude mathématique de tous les grands phénomènes sont aussi un digne et principal objet des méditations des géomètres. On doit désirer que les personnes les plus propres à perfectionner la science du calcul dirigent leur travaux vers ces hautes applications, si nécessaires aux progrès de l'intelligence humaine.' Mais, en ayant un autre but, Poisson et Fourier contribuent au développement de l'analyse, qu'ils enrichissent de méthodes, de résultats nouveaux, de notions fondamentelles. Nous allons essayer de montrer l'importance des découvertes de Poisson dans la domaine de la physique mathématique, en jétant un coup d'œil rapide sur quelques-uns de ses mémoires."

(5) Poisson was succeeded by Sturm, whose reputation is founded upon his well-known theorem in the theory of equations. M. Hermite alludes to Prof. Sylvester's discovery in this branch.

(6) In 1838, a Chair of Mécanique Physique et Expérimentale was founded, of which the first occupant was the illustrious Poncelet. Commencing with an account of the "Traité des Propriétés Projectives des Figures," the writer goes on to describe the other contributions of this eminent mathematician, who was succeeded (7) in 1851 by Delaunay. Here, again, M. Tisserand comes to the help of his colleague with an account of Delaunay's astronomical work.

(8) A short and highly appreciative account follows of Le Verrier. "Il a été donné à l'illustre auteur de ne point laisser son œuvre inachevée; Le Verrier a corrigé sur son lit de mort les dernières feuilles de la théorie de Neptune, léguant à l'astronomie un monument impérissable qui sera l'honneur de son nom et de la science de notre pays."

(9) The various works of Lamé come next under review. "Lamé est un des plus beaux génies mathématiques de notre temps. Des découvertes capitales qui ont ouvert de nouvelles voies dans la théorie de la chaleur, la théorie de l'élasticité, l'analyse générale, le placent au nombre des grands géomètres dont la trace reste à jamais dans la science."

(10) Liouville; (11) Serret; and (12) Duhamel are rapidly examined, the notice of this last being contributed by M. Bertrand.

(13) "Chasles est l'une des plus grandes illustrations de la Faculté; ses découvertes en géométrie, les ouvrages qu'il a publiés sur cette science l'ont placé au premier rang parmi les savants de l'Europe, et rendu son nom à jamais celèbre. De grandes et belles découvertes en mécanique se sont ajoutées à son œuvre principale, ainsi que des recherches d'érudition sur les mathématiques et l'astronomie des Indiens et des Arabes; nous indiquerons succinctement ces travaux qui ont jeté tant d'éclat, et sont présents à toutes les mémoires." The notice closes with the following touching sentence: "il nous reste à dire que ses amis et tous ceux qui ont connu notre cher et vénéré collègue gardent l'inaltérable souvenir de la bonté qui, chez le grand géomètre, était la compagne du génie."

(14) Cauchy is also treated at some length. "La vie du grand géomètre, remplie par des découvertes immortelles qui sont l'honneur de la science française, l'a été aussi par les œuvres de la charité chrétienne et une inépuisable bienfaisance."

(15), (16), and (17). In a few words are summed up the principal results obtained by other colleagues: "Nos collègues Puiseux, Briot, et Bouquet, morts il y a peu d'années, et dont nous gardons si affectueusement le souvenir, se sont inspirés de son génie, et ont consacré des travaux de premier ordre à poursuivre dans le domaine de l'analyse les conséquences de ses découvertes."

The speaker had a grand theme, and perhaps does not exalt too highly the very distinguished mathematicians who have preceded, or been associated with, him in his labours at the Sorbonne. One can pardon an occasional high-flown expression of his admiration for them and for their achievements: to ourselves the perusal of his discourse has furnished much pleasure, and we trust there will be as distinguished a roll of Professors to be celebrated when the work of the new Sorbonne has to be narrated by M. Hermite's successor. We conclude with the closing words of the address:—

"Nous venons d'évoquer le souvenir de nos prédécesseurs, nous avons voulu rendre hommage à leur mémoire, rappeler leurs travaux, leurs découvertes, les grands exemples qu'ils nous ont laissés. Notre mission est de continuer leur œuvre, et d'ajouter à leur glorieux héritage; ce devoir nous est rendu plus sacré par le don magnifique que nous tenons du pays, par sa généreuse assistance pour notre enseignement et nos travaux. Tous, maîtres

[1] "Discours prononcé devant le Président de la République, le 5 Août, à l'inauguration de la nouvelle Sorbonne, par M. Ch. Hermite, Professeur à la Faculté des Sciences, Membre de l'Institut," *Bulletin des Sciences Mathématiques*, January 1890 (pp. 6–36). (Paris: Gauthier-Villars.)

de conférences et professeurs, nous y consacrerons notre dévouement, nos efforts : nous avons la confiance que, pour l'honneur de la Science et de la France, nous saurons fidèlement le remplir."

SCIENTIFIC SERIALS.

The American Journal of Science, April 1890.—On the æolian sandstones of Fernando de Noronha, by John C. Branner. These sandstones lie upon the eastern or south-eastern sides of the island, at an elevation of 70 feet on Ilha do Meio, 90 feet on São José, and about 100 feet on the Ilha Rapta, and at the base of Atalaia Grande. The author has closely investigated the formation, and finds that the material was originally deposited in the form of sand-dunes blown up by winds from the south or south-east. Analyses of several specimens of the rock are given.—A mountain study of the spectrum of aqueous vapour, by Charles S. Cook. The author has devised a means of producing an artificial line whose intensity can be varied at will alongside the line whose intensity is required. The variations in the blackness of the artificial line are effected by the use of a micrometer screw, the readings of which constitute an arbitrary value of intensities. It is found, (1) that the spectroscope studies vapour height primarily, and humidity only secondarily; (2) during stormy weather vapour ascends to altitudes greater than is usually supposed; (3) the great absorption of storm clouds is due to their great thickness, or to extensive strata of damp air associated with them, more than to any peculiar behaviour as clouds.—On the occurrence of basalt dykes in the Upper Palæozoic series in Central Appalachian Virginia, by Nelson H. Darton; with notes on the petrography, by J. S. Diller.—Additional notes on the tryolite from Utah, by W. F. Hillebrand and E. S. Dana. The composition and crystalline form of this mineral are considered.—W. S. Bayley, on the origin of the soda-granite and quartz-keratophyre of Pigeon Point, Minnesota. These rocks have been previously described by the author (*Amer. Journ.*, January 1889). In the present note the reasons are pointed out which lead to the conclusion that the red rock is of contact origin, and produced by the action of the gabbro upon the slate and quartzites.—Frank Waldo, in recent contributions to dynamical meteorology, gives a general idea of the nature of each of fourteen papers on meteorology; most of the papers being by German physicists. The attitude of the writers towards meteorology is also indicated by reference to other work done in the same direction.—Two methods for the direct determination of chlorine in mixtures of alkaline chlorides and iodides, by F. A. Gooch and F. W. Mar.—On the occurrence of polycrase, or of an allied species, in both North and South Carolina, by W. E. Hidden and J. R. Mackintosh. The analyses, so far as they go, show that a mineral previously noticed (*Amer. Journ.*, November 1888) is very closely allied to, if not identical with, the polycrase from Hitteroe, Norway, analyzed by Rammelsberg.—Origin of some topographic features of Central Texas, by Ralph S. Tarr.—On the formation of silver silicate, by J. Dawson Hawkins. A simple method for the preparation of this compound is described. The reaction made use of is $Na_2SiO_3 + 2AgNO_3 = Ag_2SiO_3 + 2NaNO_3$.

SOCIETIES AND ACADEMIES

LONDON.

Royal Society, April 17.—"Preliminary Note on Supplementary Magnetic Surveys of Special Districts in the British Isles." By A. W. Rücker, M.A., F.R.S., and T. E. Thorpe, Ph.D., B.Sc. (Vict.), F.R.S.

During the summer of 1889 we carried out additional magnetic surveys of the Western Isles and the West Coast of Scotland, and of a tract of country in Yorkshire and Lincolnshire.

Both districts were selected with special objects in view. We had found that powerful horizontal disturbing forces acted westwards from the Sound of Islay, from Iona, and from Tiree, and we had deduced a similar direction for the disturbing force at Glenmorven from Mr. Welsh's survey of Scotland in 1857-58. The whole district presents peculiar difficulties, partly from the fact that local disturbance is likely to mask the effects of the regional forces, partly because the normal values of the elements must be especially uncertain at stations on the edge of the area of our survey.

If, then, the general westward tendency of the horizontal disturbing forces was due to some source of error, stations in the extreme south of the Hebrides would in all probability be similarly affected. If the directions of the forces were due to a physical cause, such as a centre of attraction out at sea to the west of Tiree, then the disturbing forces in the Southern Hebrides would almost certainly be directed southwards towards it.

The observations made last summer prove (1) that the direction of the disturbing horizontal force at Bernera, which is the southernmost island of the Hebridean group, is due south; and (2) that, as this point is approached from the north, the downward vertical disturbing attraction on the north pole of the needle regularly increases, which exactly agrees with the supposition that a centre of attraction is being approached.

There is, therefore, now no doubt that there is a centre of attraction on the north pole of the needle to the south of the Hebrides and to the west of Tiree.

(2) In one of the maps communicated to the Society last year we drew two lines, bounding a district about 150 miles long and 40 miles broad, in Yorkshire and Lincolnshire, and gave reasons for the belief that a ridge line or locus of attraction lay between them.

This conclusion has now been tested by means of thirty-five additional stations, with the following results:—

(1) At all stations (with one exception) on or near the two lines, the horizontal disturbing forces tend towards the centre of the district they bound.

(2) The downward vertical disturbing forces are greater in the centre of the district than at its boundaries. In particular, there are two well-marked regions of very high vertical force.

(3) The greatest vertical force disturbances occur at Market Weighton, where the older sedimentary rocks are known to approach the surface, and at Harrogate, which is on the apex of an anticlinal.

(4) The central ridge line runs from the Wash parallel to the line of the Wolds to Brigg. Thence it appears to turn west, and reaches Market Weighton *viâ* Butterwick and Howden. One or two additional stations are, however, required to determine whether this bend is real, or whether the line runs direct from Brigg to Market Weighton. From the latter town it passes to the limestone district of Yorkshire and traverses its centre. It has not yet been traced west of the line of the Midland Railway between Settle and Hawes, but there is ground for believing that it continues to the Lake District.

Although, therefore, one or two points of detail remain for further investigation, the existence of a line of attraction 150 miles long is proved beyond the possibility of doubt, and for about 90 miles its position is known to within 5 miles.

There are, then, even in those parts of England where the superficial strata are not magnetic, regions of high vertical force comparable in size with small counties, and ridge lines or loci of attraction as long and almost as clearly defined as the rivers. Their course is closely connected with the geology of the districts through which they run.

Royal Meterological Society, April 16.—Mr. Baldwin Latham, President, in the chair.—The following papers were read:—The cold period at the beginning of March 1890, by Mr. C. Harding. At the commencement of the month a rather heavy fall of snow was experienced in many parts of England, and very cold weather set in over the midland, eastern, and southern districts, the temperature on the 3rd and 4th falling to a lower point than at any time in the previous winter. The lowest authentic thermometer readings, in approved screens, were 5° at Beddington, 6° at Kenley in Surrey and Hillington in Norfolk, 7° at Chelmsford and Beckenham, 8° at Addiscombe, 9° at Reigate and Brockham, and 10° in many parts of Kent and Surrey. At Greenwich Observatory the thermometer registered 13°, which has only once been equalled in March during the last 100 years, the same reading having occurred on March 14, 1845. During the last half-century the temperature in March has only previously fallen below 20° in three years, whilst during the whole winter so low a temperature has only occurred in eight years.—Note on the whirlwind which occurred at Fulford, near York, March 8, 1890, by Mr. J. E. Clark. A sharp and heavy thunderstorm occurred at York about 2.30 p.m. At the same time, or shortly afterwards, a whirlwind passed a little to the south of the city, from Bishopthorpe to Heslington, a distance of about

4 miles, its width varying from 3 or 4 to 250 yards. The author made a careful survey of the track of the whirlwind, and described the damage done by it to trees, buildings, &c.—On the possibility of forecasting the weather by means of monthly averages, by Mr. A. E. Watson. The author is of opinion that the average values of meteorological phenomena are constant quantities, and that any variation from them is sure to be met by a compensating variation in the opposite direction.

Zoological Society, April 15.—Mr. G. A. Boulenger, in the chair.—Mr. A. Smith-Woodward, read a paper on some new fishes from the English Wealden and Purbeck Beds, referable to the genera *Oligopleurus*, *Strobilodus*, and *Mesodon*. Detailed descriptions of several fossils of these genera, now in the British Museum, were given. *Oligopleurus* was stated to be represented by a single species in the Wealden of the Isle of Wight, occurring also in the Purbeck of Dorsetshire; and the latter formation had yielded at least one species both of *Strobilodus* and *Mesodon*. Previous researches had already indicated a close connection between the fish-fauna of the English Purbeck Beds and that of the Upper Jurassic Lithographic Stones of France, Bavaria, and Würtemberg; and the new forms now described tended to demonstrate that alliance even more clearly.—Mr. G. A. Boulenger read the second of a series of reports on the additions to the Batrachian Collection in the Natural History Museum. Since 1886, when the first report was made on this subject, examples of 74 additional species of Batrachians had been acquired. Amongst these was a remarkable new form allied to the family Engystomatidæ, proposed to be called *Genyophryne thomsoni*, based on a single specimen obtained by Mr. Basil Thomson on Sudest Island, near South-East New Guinea. The form was stated to be unique in having teeth in the lower, but none in the upper jaw.—Mr. Frank E. Beddard read a paper on the structure of *Psophia*, and on its relations to other birds. The author was inclined to consider *Psophia* most nearly allied to *Cariama* and *Chunga*, and more distantly to *Rhinochetus*, but entitled to stand as a distinct family in the group of Cranes and their allies.—Mr. Henry Seebohm gave an account of a collection of birds from the northern part of the province of Fokien, South-Eastern China. Several interesting species were represented in the series, amongst which was a new *Hemixos*, proposed to be called *H. canipennis*.

Linnean Society, April 3.—Mr. Carruthers, F.R.S., President, in the chair.—Prof. P. Martin Duncan exhibited a transverse section of a coral, *Caryophyllia clavus*, showing septa and irregular theca between them.—Mr. B. D. Jackson exhibited some seeds of *Mystacidium filicornu*, an epiphytic Orchid forwarded from South Africa by Mr. Henry Hutton, of Kimberly.—A paper by Prof. W. H. Parker, on the morphology of the *Gallinaceæ*, in the unavoidable absence of the author was read by Mr. W. P. Sladen; and a discussion followed, in which Dr. St. George Mivart, Prof. Duncan, and Mr. J. E. Harting took part.

PARIS.

Academy of Sciences, April 14.—M. Hermite, President, in the chair.—On the theory of the optical system formed by a telescope and a plane mirror movable about an axis, by MM. Lœwy and Puiseux. One of the problems studied is to determine the exact co-ordinates of a star with a telescope and a plane mirror placed in front of the object-glass.—On the elements of peritoneal serum, by M. L. Ranvier. The humour was obtained from the domestic rabbit, the rat (*Mus decumanus*), and the cat. Microscopical examination of the preparations showed the presence of red globules of blood (hæmatics) whatever precautions were taken. It is therefore considered as a normal element, physiological, not accidental, of peritoneal serum. Colourless spherical lymphatic cells, having dimensions from 20μ to 100μ, are also described; the volume, structure, and reactions of these cells from the three animals, however, is found to vary.—On the artificial production of silk, by M. Emile Blanchard.—*Résumé* of solar observations made at the Royal Observatory of the College of Rome during the first three months of the year 1890, by M. P. Tacchini.—Observations of sun-spots made in 1889 at the Lyons Observatory, by M. Em. Marchand. The first three months of this year are also included in the list. Tables are given showing the number of days without spots, the duration and latitude of spots, and their mean total surface (umbra and penumbra) expressed in millionths of the sun's visible surface.—Approximate rectification of an arc of a curve, by M. A. E. Pellet.—Construction for the radius of curvature of symmetrical triangular curves, of plane anharmonic curves, and of asymptotic lines of Steiner's surface, by M. G. Fouret.—A paper by M. A. Ditte, on the action of nitric acid on aluminium, shows that this acid acts upon aluminium in much the same way as sulphuric acid. The slowness of the reaction is due to the formation of a protecting covering of gas. As in the case of zinc, when weak nitric acid is employed the gases produced consist of nitric oxide and nitrogen, together with some ammonia; with 3 per cent. acid in presence of a little platinum chloride, ammonia is almost the sole product. Just as with the sulphate, the nitrate forms with aluminium in presence of water a basic nitrate with liberation of hydrogen.—On the preparation of hydrobromic acid, by M. A. Recoura. The author passes a stream of H_2S through bromine, and washes the gaseous HBr produced by passing it through a solution of HBr containing a little red phosphorus in suspension. The method admits of the production of gaseous HBr at any desired rate, and without the necessity of the continual watching required by the methods formerly employed.—On the oxidation of hypophosphorous acid by hydrogenized palladium in the absence of oxygen, by M. R. Engel. In the precipitation of palladium by hypophosphorous acid according to the method followed by Wurtz and Graham, the author finds that the product, contrary to the statements of those investigators, contains hydrogen. The spongy palladium produced decomposes an unlimited quantity of phosphorous acid, hydrogen being evolved.—M. P. Cazeneuve contributes a paper on the oxidizing and decolorizing properties of charcoal.—M. E. Jungfleisch, in a note on camphoric acids, shows that the separation of several acids is possible when advantage is taken of their differing solubilities.—A note on the acid malonate, the quadromalonate, and the quadroxalate of potassium, by M. G. Massol, gives the thermal properties of these salts, and an analysis of the quadromalonate.—M. L. Lindet describes a method for the extraction of raffinose from molasses, and for the separation of raffinose from saccharose, the separation depending upon the greater solubility of raffinose in absolute methyl alcohol, and its much inferior solubility in 80 per cent. ethyl alcohol, as compared with the solubility in each medium of saccharose.—On a pseudo-typhoid bacillus found in river water by M. Cassederat. The author has found in Marseilles drinking-water a bacillus having a great resemblance to that of typhoid fever. The investigations, so far as they have gone, seem to fully establish the identity of the two bacilli.—On the microbes of hæmoglobinuria of the bull, by M. V. Babes. An examination of the character of this organism shows that it has no well-established place in the classification of microbes, and that the conditions of culture are not yet well determined. Nevertheless, its special reactions, its localization in the red globules, and its transmissibility to animals, leave no room for doubt as to its pathological significance.—Nutrition in hysteria, by MM. Gilles de la Tourette and H. Cathelineau. It is noted that in hysteria, notwithstanding nervous pathological manifestations other than permanent affections, nutrition is effected normally.—On operation for strabismus without tenotomy, by M. H. Parinaud.—On the function of air in the physiological mechanism of hatching, sloughing, and metamorphosis among Orthopterous insects of the family Acridides, by M. J. Kunckel d'Herculais.—On a new Lycopodium of the Coal-measures (*Lycopodiopsis Derbyi*), by M. B. Renault.—Pebble impressions, by M. Ch. Contejean. The paper refers to Tertiary pudding-stones found near Montbéliard.

BERLIN.

Physiological Society, March 28.—Prof. du Bois-Reymond, President, in the chair.—Prof. Salkowski spoke on fermentative processes which occur in animal tissues, employing chloroform-water to discriminate between the action of ferments (organized) and enzymes (unorganized). He had thus found that a fermentation (zymolysis) occurs in yeast-cells, by which their cellulose is partly converted into a lævo-rotatory sugar and the nuclein into substances of the xanthin series. He had further isolated from yeast-cells, apart from their cellulose, two other carbohydrates, one belonging to the gum series and one resembling glycogen; either of these might have been the source of the above-mentioned sugar. In a similar way he had studied the fermentative changes which take place in liver and muscle, and found them to yield a series of distinct products which could be determined both qualitatively and quantitatively. He concluded from his researches that fermentative (zymolytic) processes are continually taking place in living tissues, and play a most

important part in the chemistry of their metabolism.—Dr. Rosenberg demonstrated a new reaction of uric acid. When urine is made faintly alkaline, it yields a dark blue colouration on the addition of phosphotungstic acid, which he had satisfied himself was due to the presence of uric acid alone among the other constituents of the excretion.—Dr. Goldscheider gave an account of some experiments which he had made some five years ago, to show that the principle of "specific nerve energy" holds good for the sense of taste. By isolated stimulation of separate taste-papillæ he succeeded in showing that there exist, in all, four kinds or qualities of taste—sour, sweet, bitter, and salt; and that specific end-organs exist for each kind of taste. By electrical stimulation there arises at the anode not only the sensation of sour, but also of bitter and sweet; at the kathode purely sensory impulses are aroused in addition to the gustatory, and to the fusion of these two is due the "alkaline" taste of which some authors speak. It appeared from his researches that the hard palate contained end-organs chiefly for the perception of sweet tastes.—Dr. I. Munk spoke on muscular work and nitrogenous metabolism. He criticized the recent work of Argutinsky, according to which the work done in climbing a mountain, and the heat produced, are the outcome of a breaking down of nitrogenous material. Having recalculated Argutinsky's results, he came to the conclusion that (1) his body was not in nitrogenous equilibrium even during rest; (2) the amount of carbohydrate which he took was insufficient to account for the heat-production during rest. As is well known, both these factors lead to an increased nitrogenous metabolism when extra work is done, the energy required for the excess of work being obtained from the breaking down of proteids; hence no conclusions as to what normally takes place can be drawn from Argutinsky's experiments. He further pointed out that Oppenheim's experiments have shown that dyspnœa leads to increased nitrogenous metabolism, and that hence dyspnœa may very probably have played some part during the exertion of excessive climbing. While not doubting the accuracy of the experiments, he did not feel that the conclusions which Argutinsky had drawn from them were justifiable.

GÖTTINGEN.

Royal Society of Sciences, Oct. 15, 1889.—On the granular pigments occurring in man, by Dr. F. Maas. Two chemically distinct groups of pigments occur: (1) melanin, (2) the granular colouring matters here referred to. The latter are found at all periods of life, but increase in quantity and in the size of the granules with age. They are normal products, not morbid. They are not only transformed but produced by the corpuscle-carrying cells. They are not wholly derived from the blood: the pigment found in the heart is derived from a fatty body. The several pigments can be distinguished by their reactions with hydrochloric and acetic acids, and with caustic potash.—On the analogue of Kummer's surface for $p = 3$, by W. Wirtinger. The author investigates the continuum obtained by taking, as the eight homogeneous point-co-ordinates of a 7-dimension space, eight linearly independent squares of theta-functions of three variables. It appears that this possesses collineations analogous to the system for Kummer's surface, as also the corresponding system of reciprocal transformations into itself.

October 23, 1889.—Determination of the elastic constants of Iceland spar, by W. Voigt. The author uses the refraction observations of G. Baumgarten, and gives elaborate tables of his own measurements. He discusses the property of spar by which the crystal can be forced by shearing into its twin form, and gives diagrams illustrating the changes in the traction and torsion coefficients.—Determination of the elastic constants of certain dense minerals, by W. Voigt and P. Drude. The minerals are dense fluor spar, Solenhofen stone, and dense barytes.

December 3, 1889.—On thermo-electric currents in crystals, by Th. Liebisch. The author confirms some of Bäckström's results, and finds that, in a rectangular parallelepiped of homogeneous conducting crystal of the triclinic system, embedded in homogeneous isotropic "normal" metal, "the thermo-electric force in the direction of the steepest temperature gradient is represented by the squared reciprocal of the parallel radius vector of a certain ellipsoid E."—On contrast-phenomena resulting from suspended attention, by Dr. F. Schumann. Psychophysical experiments on the estimation of short periods of time, &c.

December 25, 1889.—On the fertilization of the ova of *Agelastica alni*, L., by Dr. H. Henking. In this insect it is observed that in ova taken from the oviducts a number of spermatozoa penetrate deeply among the yolk-masses as far as the level of the female pronucleus. Peculiar karyokinetic appearances are described.—Contribution to the theory of the even Abelian sigma-function of three arguments, by Ernst Pascal. This is a continuation of the author's previous work on the odd sigma-function. The terms of the developments are combinants of a net of quaternary quadratic forms.—On a hyperelliptic multiplication equation, by H. Burkhardt. This equation for hyperelliptic functions ($p = 2$) is the generalisation of Jacobi's equation for elliptic functions.

AMSTERDAM.

Royal Academy of Sciences, March 29.—Prof. van der Waals, Vice-President, in the chair.—M. H. A. Lorentz dealt with the molecular theory of diluted solutions. He showed how the known formula for the vapour-pressure of such solutions may be derived from considerations on molecular motion and attraction, and how a similar theory applies to a conceivable mechanism of osmotic pressure.—M. Baehr gave some observations on the herpolhodie of Poinsot, and explained that this cannot have any points of inflexion, unless the ellipsoid be not a central one.—M. Pekelharing spoke of "the destruction of anthrax spores by rabbits' blood."

STOCKHOLM.

Royal Academy of Sciences, April 9.—On the researches in zoology made at the Zoological Station of the Academy during 1889, by Prof. S. Lovén.—On the possibility of the triangulation of Spitzbergen, by Prof. Rosén.—An analysis of the liquid inclosures in topaz, or the so-called Brewsterlinite, by Otto Nordenskiöld.—On the use of invariants and seminvariants for the solution of common algebraic equations of the four lowest degrees, by Dr. A. Bergen.—On the structure of the fruit-wall in the Labiatæ, by Miss A. Olbers.—Some researches on accidental double refraction of gelatinous substances, by Dr. G. Bjerkén.—On the action of iodohydric acid on 1·5 nitronaphthalin-sulphon-acid-amid, by A. Ekbom.

THURSDAY, MAY 1, 1890.

THE APPLICATION OF THE MICROSCOPE TO PHYSICAL AND CHEMICAL INVESTIGATIONS.

Molekularphysik, mit besonderer Berücksichtigung mikroskopischer Untersuchungen und Anleitung zu Solchen, sowie einen Anhang über mikrochemische Analyse. Von Dr. O. Lehmann, Professor der Electrotechnik am kgl. Polytechnikum zu Dresden. 2 Volumes, pp. 852, 697, with 624 Woodcuts and 10 Plates. (Leipzig: W. Engelmann, 1888–89.)

VERY soon after the first invention of the microscope, attempts were made to apply the new instrument to solve some of the remarkable problems of crystallogenesis. The early volumes of the Royal Society Transactions contain in the papers of Boyle, Hooke, and Leeuwenhoek, published between the years 1663 and 1709, many records of attempts of this kind; and the works of Henry Baker, which appeared between 1744 and 1764, are also largely concerned with the study of the process of crystallization under the microscope.

In Germany, Ledermuller in 1764 and Gerhardt in 1780 showed the value of the microscope in studying the internal structure of crystals; while in France a long succession of enthusiastic investigators, Daubenton, Dolomien, Fleurian de Bellevue, Cordier, and others, were busily engaged in laying the foundations of the science of microscopical petrography.

Early in the present century, we find the English investigators once more taking a leading part in applying the microscope to the study of crystallized bodies. Between the years 1806 and 1862, Brewster published a long series of memoirs, dealing with the microscopical characters of natural and artificial crystals, and the inclusions which they contain. About the year 1850, too, Mr. Sorby commenced his important investigations on the subject, availing himself of the method of preparing transparent sections of rocks and minerals which had been, shortly before this time, devised by William Nicol. Mr. Sorby's epoch-making memoir "On the Microscopical Structure of Crystals, indicating the Structure of Minerals and Rocks" made its appearance in 1858.

While one group of investigators, following the lines of the early work of Brewster and Sorby, have sought to make the microscope an efficient instrument for the determination of minerals, even when present in rocks as the minutest crystals or fragments; others have no less diligently pursued the methods which the same pioneers in this branch of research have initiated for solving physical and chemical problems connected with the formation of crystallized bodies.

In the hands of Des Cloizeaux, Tschermak, Zirkel, Von Lasaulx, Fouqué and Michel-Lévy, Rosenbusch, and other workers, the microscope has gradually been developed into a splendid instrument of mineralogical research; and the determination of the minutest particles of a mineral is now becoming no less easy and certain than that of the largest hand-specimens.

But, at the same time, Brewster and Sorby's early attempts to solve physical and chemical problems by the aid of the microscope have not failed to exercise an important influence on subsequent workers in these branches of science. Link, Frankenheim, Klocke, Harting, and especially Vogelsang (whose early death was a very severe loss to this branch of science), have done much towards establishing the science of crystallogenesis upon a firm basis of accurate observation; and their labours have been continued in more recent times by H. Behrens and Dr. Otto Lehmann, the author of the work before us.

As the well-known treatises of Rosenbusch, and of Fouqué, Michel-Lévy, and Lacroix, give us an admirable *résumé* of the present state of determinative mineralogy, as improved by the application of the microscope, so does the work before us contain a perfect summary of the contributions of the microscopist to the sciences of physics and chemistry.

It will only be possible, within the limits of an article like the present, to indicate briefly the plan of the very comprehensive, and, indeed, almost exhaustive work, in which Dr. Lehmann has embodied the observations of himself and his predecessors in this field of inquiry.

The first division of the book deals with the construc-

tion and use of the microscope; especial attention being given to forms of the instrument, like those devised by Nachet and by the author of this work, for the special purpose of studying crystallization and other physical and chemical processes.

The second division of the book treats of those physical properties of matter which are presented by all bodies, whether in the solid, liquid, or gaseous state. Such questions as the polarization and absorption of light, the conduction of heat, and the electric and magnetic relations of various substances are here dealt with by the author.

The next division relates to the peculiar properties presented by solids. Elasticity and plasticity are considered, and, under the latter head, the remarkable phenomenon of the production of twinned structures in crystals by mechanical means is fully discussed. Under the head of cleavage we find a treatment of such phenomena as the production of mathematical figures in certain crystals by pressure, percussion, &c.; while under the heads of "Enantiotropic" and "Monotropic" are classified the consequences which follow from heteromorphism among crystalline substances, and the tendency of the heteromorphous forms to pass one into the other.

The division dealing with liquids and their peculiar properties contains discussions on fluidity, surface-tension, diffusion, capillarity, and crystal-growth, with the origin of structural anomalies. The problems of solution and precipitation, with those of solidification and fusion, are also treated of in this part of the treatise.

The second volume of the work commences with the discussion of the properties of gases and their relations to solids and liquids. This division of the subject, which is very exhaustively treated, extends to 335 pages.

The work concludes with critical remarks upon different molecular theories. The chapters dealing with the theories of crystal structure, of allotropy, of heteromorphism, and of isomerism, with several others, in the same division of the book, are full of interest and suggestiveness.

A supplement of about 150 pages is devoted to what the author calls "crystal-analysis," or what is generally known to geologists and mineralogists as "microchemical analysis." Very minute particles of an unknown substance may often be determined by being treated with appropriate reagents and studied under the microscope; in this way they are made to yield crystals of various compounds which can be recognized by their characteristic forms and habit. An admirable summary is given by the author of the work of Bořický, Streng, Behrens, Haushofer, and others, who have gradually perfected this branch of research, and made the method one which is of the very greatest service to the students of microscopical mineralogy and petrography.

While the physicist and chemist will find in this work a perfect mine of interesting and ingenious experiments (many of which are suited to class-demonstrations by projection methods), the mineralogist and geologist will hail the appearance of the book as one that completes and supplements the well-known treatise of Vogelsang—a work that has exercised the most important influence on the development of petrological theory.

In conclusion, it may be pointed out that, not only are the numerous observations of the author on crystallogenesis that are described in memoirs in *Groth's Zeitschrift* included in the work before us, but many others that have never before been published find a place in these volumes. The work is very fully illustrated both with woodcuts and coloured plates, and constitutes a complete synopsis of all that is known on a number of questions of great importance and interest to workers in many different branches of science.

BERTRAND ON ELECTRICITY.

Leçons sur la Théorie Mathématique de L'Électricité, professées au Collège de France. Par J. Bertrand. (Paris: Gauthier-Villars.)

THIS book contains lectures on electricity given by M. Bertrand at the Collège de France. In his preface the author states that he has confined himself to the mathematical principles of the subject; but this hardly expresses the limitation he has imposed upon himself, for a great many results which English students of electricity are accustomed to find in text-books on this subject are omitted from this work. A brief description of the contents of the book will suffice to show this. The first chapter contains an investigation of the attractions of spheres and spherical surfaces when the law of attraction is inversely as the square of the distance; the second and third are devoted to the properties of the potential; the fourth contains an investigation of the conditions under which the method of lines of force can be used; the fifth, which has the comprehensive title "Électricité Statique," contains a short discussion of the electrical distribution on two spheres which mutually influence each other, the reciprocal theorems, and a discussion of the properties of the Leyden jar so far as they can be discussed without introducing the idea of specific inductive capacity; the sixth chapter contains some remarks upon magnets; the seventh treats of Ohm's law, and contains Kirchhoff's equations for the distribution of currents amongst a network of conductors, without, however, any applications even to such an important case as that of Wheatstone's bridge; the eighth, ninth, and tenth chapters contain, respectively, investigations of the magnetic forces produced by linear currents, the laws according to which such currents act on each other, and simple applications of these laws; the eleventh chapter contains some account of the induction of currents, and, amongst other things, some well-founded reasons for not deducing the laws of induction from the principle of the conservation of energy alone, but no hint is given of the possibility of regarding a system of currents as a dynamical system, though the introduction of this idea by Maxwell has thrown new light over the whole subject and enabled many of the properties of currents to be recognized at once as those belonging to any dynamical systems; the twelfth chapter contains some account of the application of the results of the previous chapters to dynamo-electric machines; and the thirteenth and last chapter discusses units.

There are two views which have been taken as to the relation between the mathematics and the physics, which ought to exist in a text-book on mathematical physics: the one is, that it is the province of physics to supply the

laws of action between particles charged with electricity, elements of current, and the like; then its function ceases, and the rest is a mere matter of mathematical symbols; by this method the physics and the mathematics are sharply divided—the physics occurs in the first few lines of the chapter, the rest of which is mathematics. In the other method the physics and mathematics are kept as closely connected as possible, so that by knowing from physics the kind of results we may expect errors in the mathematical investigations may be detected while, on the other hand, our physical conceptions may be extended, and perhaps even the point of view changed, by the results of mathematical transformations. Thus, as Maxwell points out, the two sides of the equation which expresses Green's theorem might have suggested the two ways of regarding electrical phenomena—the one when we confine our attention to the electrified bodies; the other when we look upon the dielectric as the seat of the phenomena. In the department of physics in which mathematical analysis has won perhaps its greatest triumphs, that of gravitational attraction, the first method is perhaps the most natural; but in an intricate subject like electricity, where so much remains to be discovered, and which it is so important to regard from as many points of view as possible, the second method seems infinitely the more likely to lead to an extension of our knowledge.

M. Bertrand's work is a most favourable example of the first method: it is clearly and gracefully written, and the mathematical part often extremely elegant; yet, in spite of all this, we must confess to a feeling of disappointment on reading the book. We had thought from the publication of Mascart and Joubert's "Leçons sur l'Électricité et le Magnétisme," and the excellent translation of Maxwell's "Electricity and Magnetism" by MM. Seligman-Lui, and Cornu, that the ideas introduced by Maxwell, von Helmholtz, and others, were spreading in France; yet here we have a work written by one of the first scientific men of that country, in which the subject is treated in fundamentally precisely the same way as that in vogue twenty or thirty years ago; and in fact, with the exception of some results due to M. Marcel Deprez, in the chapter on electro-magnetic machines, there is no reference to any investigation made within the last twenty years. The names of Maxwell and von Helmholtz are not even mentioned in the book itself—though, to be quite accurate, that of Maxwell occurs in the table of contents in connection with a particular case of Green's theorem.

M. Bertrand seems to exact more from the science of electricity, before he deems it worthy to be discussed mathematically, than is exacted from any other science; thus, for example, he omits all consideration of the effect of the dielectric because there is no satisfactory molecular theory of specific inductive capacity, such as Mossotti attempted by supposing the dielectric to contain conducting spheres, the specific inductive capacity depending on the ratio of the volume of the spheres to that of the rest of the dielectric. It seems to us that if M. Bertrand were to write a book about optics, he would, if he were consistent, leave out everything connected with either refraction or reflection, since no complete molecular theory of these phenomena have been given. The way in which the dielectric affects the lines of force is as definite and simple as the way in which a refracting medium affects the rays of light, and the one is quite as capable of receiving mathematical treatment as the other.

Again, M. Bertrand, in treating of magnetism, points out that on the theory of magnetic fluids the behaviour of a magnetized body will depend upon the shape of the molecules, and as this is not known he refuses to investigate the magnetic properties of bodies; he never mentions magnetic permeability, the idea of which, by introducing a new property of bodies, enables us to investigate mathematically their magnetic properties, and express the results of the investigation in terms of quantities which can be measured in a physical laboratory.

In spite of the clearness and elegance of this book, we are afraid that a student who learnt his electricity from it would think, if he read any modern memoirs on the subject, that they dealt with some new and unknown science; for the mode of regarding the phenomena would probably be entirely different, and many quantities would be introduced of whose existence M. Bertrand had given him no hint.

OUR BOOK SHELF.

Sundevall's Tentamen [*Methodi naturalis avium disponendarum tentamen*]. Translated into English, with Notes, by Francis Nicholson, F.Z.S., &c. (London: R. H. Porter, 1889.)

THE practice of translating into English memoirs by leading foreign naturalists that may be considered classical is to be highly commended. English ornithologists who are not conversant with German may thus study such important works in their branch of science as Nitzsch's "Pterylographie" and Johannes Müller's "Voice Organs of Passeres," of both of which excellent English translations exist.

It is, however, a question whether Sundevall's "Tentamen" comes into the category of classical memoirs, or is worth translating if it does. In our opinion it might have been allowed to drop peacefully into oblivion in the obscurity of the original Latin. No particular object is gained by helping to perpetuate a scheme of bird-classification like that of Sundevall, with the details of which no one nowadays can agree. Even the translator has nothing to say for it, except the very general statement that "every serious scheme of classification contains some items of progressive knowledge towards the attainment of a complete natural arrangement of the class of birds." It would be very difficult, however, to say what these items are, and the translator gives us no help in the matter. On the other hand, if ornithologists believe that this, the last work of Sundevall, is really important, then it can be certainly said that Mr. Nicholson's translation is good and accurate.

The introduction, which occupies the first twenty-five pages, is interesting, and so are the notes interspersed through the volume; but it is clear that the book must be entirely judged by the merits or demerits of the scheme of classification. Prof. Newton (article "Ornithology," in "Encyc. Brit.," ninth edition) has subjected Sundevall to a searching criticism, which seems to us to be perfectly justified. Some of the worst features of the classification—in addition to those mentioned by Prof. Newton—are to associate *Serpentarius* with any other birds of prey, to place the American vultures near the American kites (an error which is constantly cropping up in spite of the obvious anatomical differences), *Glareola* among the goatsuckers, &c. Prof. Sundevall's classification is, in fact, most reactionary in every particular; it is difficult to believe that it was published in the year 1872—after the appearance of so many important papers upon bird classification and structure, such as those of Profs. Huxley and Parker.

Mr. Nicholson very justly remarks in a footnote to p. 43, that since the publication of the "Tentamen," much has been done in the way of improvement in the classification of birds. In order to assist the student a few references are added to recent publications.

These do not seem to be very well chosen; for example, it is probably much better to arrange the Turdidæ in two sub-families, as has been suggested later, than to retain Sundevall's arrangement. But this seems a very trifling matter in comparison with such serious errors as we have referred to, about which there can be no question, and which are left altogether unnoticed by the translator. F. E. B.

The Flowering Plant: as illustrating the First Principles of Botany. By J. R. Ainsworth Davis, B.A. (London: Charles Griffin and Co., 1890.)

DIFFERENT opinions may be held as to what constitutes an elementary science text-book dealing with first principles, and we are inclined to think that Mr. Davis has given the work before us too modest a title. This little book, of 160 pages, contains enough facts and "hard words" to fill a small Encyclopædia, although "no previous knowledge is assumed"; and we fear that any beginner who limited his studies to this work would run more danger of developing into a kind of living abridged botanical dictionary than of mastering the first principles of the science.

The introduction, which deals with "the scope and subdivisions of the subject," "differences between plants and animals," and "differences between living and non-living matter," is condensed into 5½ pages. The following 137 pages are devoted to morphological and physiological botany; these are succeeded by an appendix on practical work, in which directions for the description of flowering plants, a summary of the various classes and orders, and directions for the study of anatomy, histology, and physiology, are condensed into 15 pages. One cannot help being struck by the author's power of *précis*-writing.

We cannot, therefore, recommend Mr. Davis's book to beginners, for whom a judicious selection of facts from which main principles may be deduced is, in our opinion, necessary. It is no easy task to write a book on "first principles," and this can hardly be accomplished by any-one who has not devoted much time to actual observation in the subject in question.

In his preface the author states that "no attempt has been made to 'write up' (or 'down') to any syllabus;" but the title-page informs us that the book is "especially adapted for the London Matriculation, South Kensington, and University Local Examinations in Elementary Botany." This, we take it, explains the real object of the work, which is also indicated by an appendix, consisting of 153 questions selected from South Kensington and London University examination papers. The appearance of the present work is, in fact, a natural result of our present system of examinations.

Looked upon as a set of condensed notes, reca what has been learnt in lectures which (as doubtless many at the present time *have* to be) are "specially adapted for the requirements" of various examinations, the book may certainly prove useful to many, and from this point of view much might be said in its favour. Moreover, as no specific types are taken, it will probably (for examining bodies do fortunately change their "types" occasionally) have a longer life than the author's "Text-book of Biology."

It is impossible here to criticize the work in detail, and we will only call attention to the insufficient account of growth contained in the introduction: such condensation cannot but result in inaccuracy.

Sixty figures are included in the text, most of which are very well known; some half-dozen are original, but most of these might have been omitted with advantage.

Cycles of Drought and Good Seasons in South Africa. By D. E. Hutchins, Conservator of Forests, Knysna. With Cyclical Diagrams. Pp. 137. (London: William Wesley and Son, 1889.)

MR. HUTCHINS'S little book consists of two lectures (subsequently amplified) which were delivered at King William's Town and Grahamstown in 1886 and 1887. Their subject-matter is fairly indicated in the title, and the author's views are succinctly set forth in the opening words of his second lecture:—"We know that the climate of South Africa varies in cycles, that the climates of other countries similarly placed, such as Australia, South America, and India, also vary in cycles. This cyclical variation is probably due to more causes than one."

Of these cycles, one only, that of the sun-spot period, is already familiar to meteorologists. The others are—a cycle of 9 or 10 years, or, more accurately, 9·43 years as a mean, which Mr. Hutchins terms the "storm cycle," and appears to have been suggested to him by the rainfall register of Cape Town Observatory, extending over 48 years; and one of 12 or 13 years, which he terms the "cyclical mitigation" of the droughts which otherwise prevail in the intervals of the maxima of the two previous cycles. The physical cause of this last is not indicated. Allowing for an occasional delay of a year in the occurrence of the sun-spot rainfall maximum, the vicissitudes of the Cape Town Observatory rainfall are thus fairly reduced to rule. For other stations some modifications are found necessary, and it appears that at certain inland stations and on the east coast a wet year occurs two or three years after that of maximum sun-spots, which Mr. Hutchins terms the "lag rain" of sun-spot maximum. In the register of the Karoo rainfall we also notice a year of "irregular mitigation," and another year of high rainfall not reducible to any cycle, but which is not so annotated.

Perhaps, indeed, we are wrong in assuming that some of the above cycles are new and unfamiliar, since Mr. H. C. Russell, in a paper communicated to the Royal Society of Sydney in 1876, tells us that cycles of 2, 3, 5 or 6, 6 or 7, 9, 10, 11, 12, 13, 17, 19, 30, and 56 years, have been advocated as regulating the rainfall of different places, and we might, of our own knowledge, add others to the list. But with the exception of the sun-spot cycle, all of them seem to be evolved from the rainfall statistics dealt with in each case, and to have no other physical meaning.

It does not seem to have occurred to Mr. Hutchins that, however ingenious as an arithmetical exercise, such analyses of a series of statistics have no more claim to rank as physical inquiry than the solving of acrostic puzzles. He has evidently no misgiving on this head, and is certainly not open to the reproof conveyed in Montrose's well-known lines. He does not fear the fate of his system too much to put it to the touch of a definite and detailed forecast; and under its guidance he has constructed tables showing year by year the occurrence of drought or of average or excessive rain, in some cases for the next half-century. Those therefore who may live to the year 1938 will be in a position to form a definitive judgment on the merits of the system. H. F. B.

Science in Plain Language. By William Durham, F.R.S.E. (Edinburgh: A. and C. Black, 1890.)

MR. DURHAM thinks that there are many intelligent persons who have not time, and may not have the inclination, to read regular scientific works, but who would be glad to know the general results of scientific investigation if these results could be set forth in plain language without too much detail. For this class he has written the present volume, which consists of articles that were originally printed in the *Scotsman.* The subjects are divided into four groups—natural selection, protoplasm, colour, and movement. Under "Natural Selection" there are essays on the origin of species, evolution, the evolution of man, the origin of man's higher nature, the

antiquity of man, primæval man, and ancient lake-dwellings. The section on "Protoplasm" includes papers on the origin of life, the basis of life, bacteria, disease germs, and fermentation. Under "Colour" we find articles on the colour of flowers, the colour of animals, and warning colours and mimicry. "Movement" takes in essays on movements in plants, the sleep of plants, climbing plants, and carnivorous plants. Discussing so many subjects, the writer is, of course, obliged to content himself with the statement of very wide views; but his expositions are so clear and fresh that the book ought to be of considerable service to the readers to whom he specially appeals. It will give them at least a general conception of the nature and direction of some of the lines of modern research, and may induce them to seek elsewhere for fuller knowledge.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Panmixia.

I REGRET that I was led to doubt the sincerity of Mr. Romanes when he professed to have formed the conclusion that my words meant the reverse of their plain significance. I had not supposed that there was any one capable of making such a mistake.

I should be glad to terminate this discussion by a brief statement of the divergence of view between Mr. Romanes and myself as to the original matter in question, from which Mr. Romanes has led the correspondence by raising a variety of collateral issues. At the same time I should like to take the opportunity of saying what I believe Mr. Romanes would reciprocate, viz. that there is no ill-feeling but only a divergence of opinion between us.

Mr. Romanes definitely states that when an organ has become useless it will decrease in successive generations as a result of "cessation of selection" to about half its original size, without the co-operation of any such cause as economy of growth. He has repeated in effect this statement in his last letter. The result attributed by him to mere cessation of selection is, it must be noted (because he shows a tendency to waver and to substitute "degeneration" for "decrease in size"), a *decrease of size*: a mere failure in the exact adjustment of the parts of a complex organ is *not* the result in question. Of this I have a few words more to say below.

Mr. Romanes not only attributes the decrease in size of a useless organ to the cessation of selection pure and simple, but he calls that condition "a causal principle," and claims to have discovered it.[1] He has also stated that, whilst (to use his own words) "inherited decrease" of an organ *must* be due to this principle, it is "remarkably strange" that Mr. Darwin had overlooked it, and that it was unfortunate that he (Mr. Romanes) only gained the idea of this novel principle just after the appearance of the last edition of the "Origin of Species."

On the other hand, I consider that Mr. Romanes, by these contentions, obscures the theory of organic evolution, and that he presumes to censure Mr. Darwin without cause. There is nothing unfortunate in the date of Mr. Romanes's idea, because the idea is entirely erroneous; and it was no strange oversight of Mr. Darwin not to attribute the decrease of useless parts to "the principle of cessation of selection," or, in other words, to their uselessness alone—for the simple reason that he would have made a blunder had he done so. It is this blunder which Mr. Romanes places before us as his own contribution to the theory of panmixia: it is this blunder which Mr. Darwin not only did not make, but rendered *almost* impossible for others by his discussion of the matter ("Origin of Species," p. 401).

It is an incontrovertible mathematical fact that *the only effect of promiscuous breeding or panmixia* (considered apart from all other influences) *upon an organ or part which presents variations round an average mean will be to increase the number of individuals near the average mean, in proportion to the number of generations in which the panmixia is operative.* The notion that the hap-hazard interbreeding of "variations about a mean," must by itself lead to a shifting of the mean in the direction of diminished size—without the assistance of any special cause favouring reduction in size—is, to put it plainly, absurd.

It is, I believe, a mistake on the part of Mr. Romanes to say that Galton, Weismann, and Poulton agree with him in this astonishing fancy. But, were this the case, the mathematical fact would remain as it is.

Given a race of organisms in which a part has become useless, it is only (as Mr. Darwin pointed out) when some cause (such as economy of growth) favouring diminished size is operative, that the average mean of the size of the part will in successive generations shift in the direction of decrease. Mr. Darwin saw this, and explained it. Mr. Romanes not only failed to appreciate the considerations advanced by Darwin, but actually now charges him with oversight for not having made the blunder which he carefully avoided.

In conclusion, I have a few words to say in regard to the possibility of an organ consisting of several nicely adjusted parts losing that adjustment in a state of panmixia without the co-operation of economy of growth. Mr. Romanes erroneously declares that if we admit this we must also admit that decrease in size must similarly result. I am not surprised to find that he thinks so, and do not doubt his sincerity. But really the two cases present very different problems. Suppose the organ in question to be represented by fifty independent variables; then we have to consider not the probability of the average mean of each kind of variable being maintained but the probability of the production of the necessary *combinations* of fifty of them with the specific initial proportions of each of the fifty elements. Whether it is or is not probable that the complex adjustment and interaction of parts would be maintained in the absence of all interfering causes in a state of panmixia is a difficult question. It is one which is hardly worth further discussion, since it is impossible that the results of panmixia without such interfering causes should ever present themselves in organic nature.

It is, moreover, quite certain that any conclusion we may adopt in regard to that matter will not alter the mathematical fact that, given a numerous race and a long series of generations, the average mean round which the variations in size of a useless organ are distributed will not ultimately shift in the smallest degree either towards increase or decrease of size, as the result of the promiscuous interbreeding of the variations.

April 26. E. RAY LANKESTER.

[1] The erection of a negative condition—a cessation—into the position of a causal principle is an artifice which is very likely to obscure the view of the related facts. The "causal principle of non-existence" and "the reversal of being," would be worthy of the author of the artifice who professes also to have extracted an essence from an idea—the idea of promiscuous breeding, or panmixia!

The Inheritance of Acquired Characters.

IT surprises me to find that anyone who has looked into the evidence can doubt that acquired characters, as distinct from congenital ones, may, like congenital characters, become hereditary, and produce physiological effects. The instance mentioned in Herbert Spencer's letter in NATURE (vol. xli. p. 511), of domestic varieties of animals losing the power of erecting the ears, appears as nearly conclusive on the subject as such an instance can be.

On the habits or instincts of domesticated varieties, Darwin says:—"It may be doubted whether anyone would have thought of training a dog to point, had not some one dog naturally shown a tendency in this line. . . . When the first tendency to point was once displayed, methodical selection and the inherited effects of compulsory training in each successive generation would soon complete the work" ("Origin of Species," 4th edition, p. 256).

I quote another instance from Carpenter's "Comparative Physiology" (p. 987):—"Sir C. Lyell mentions that some Englishmen, engaged in conducting the operations of the Real del Monte Company in Mexico, carried out with them some greyhounds of the best breed to hunt the hares which abound in that country. It was found that the greyhounds could not support the fatigues of a long chase in this attenuated atmosphere, and before they could come up with their prey they lay down gasping for breath; but these same animals have produced whelps which have grown up, and are not in the least degree incommoded by the want of density in the air, but run down the hares with as much ease as do the fleetest of their race in this country."

Mr. Gulick's letter in NATURE (vol. xli. p. 536), insisting that the first and only absolutely essential factor in the

production of new varieties or species is the isolation of a portion of the race, appears very luminous. On this subject, let me again quote from Darwin:

"Youatt gives an excellent illustration of the effects of a course of selection, which may be considered as unconsciously followed, in so far that the breeders could never have expected, nor even have wished, to produce the result which ensued—namely, the production of two distinct strains. The two flocks of Leicester sheep kept by Mr. Buckley and Mr. Burgess, as Mr. Youatt remarks, 'have been purely bred from the original stock of Mr. Bakewell for upwards of fifty years. There is not a suspicion existing in the mind of anyone at all acquainted with the subject that the owner of either of them has deviated in any one instance from the pure blood of Mr. Bakewell's flock, and yet the difference between the sheep possessed by these two gentlemen is so great that they have the appearance of being quite different varieties'" ("Origin of Species," 4th edition, pp. 37, 38).

JOSEPH JOHN MURPHY.

Belfast, April 24.

THE fifth caudal vertebra of a tortoiseshell cat at the Sussex County Hospital is dislocated and attached at right angles to the long axis of the fourth. The sixth and last vertebra is also affixed at right angles to the fifth. The cat is able to wag the terminal phalanx of the tail, and the distortion has always been considered to be due to an accident when the animal was a kitten. Within the last week the cat has had a litter of several kittens, two of which were born almost tailless, one possessing (as far as I could ascertain by external manipulation) two caudal and the other three caudal vertebræ only. Whether the original distortion is due to accident or not, I think these facts may interest some readers of NATURE.

W. AINSLIE HOLLIS.

Brighton, April 28.

P.S.—Since writing the above note I have had an opportunity of examining the two remaining kittens of the litter, and I find that only one of these has a normal tail. The other is docked of one or two of the terminal vertebræ, and the tail has a slight twist on itself towards the end.

April 30.

Variation in the Nesting-habits of Birds.

IN considering the interesting question of instinct, one naturally turns to the nesting-habits of birds as affording an apparently good instance of habit acquired and perpetuated so as to become fixed, and, as we say, instinctive. It would be interesting, however, to find exactly how far the art of nest-building is really inherited, and how much uniformity exists among the nests of birds of identical specific characters.

The "blackbird" of this region, *Scolecophagus cyanocephalus*, is rather noteworthy in this connection. Goss, in his "Birds of Kansas," says this bird breeds in trees and bushes, from three to thirty feet from the ground. In Colorado, as observed by Mr. Morrison and myself, it breeds sometimes on the ground, and sometimes in low trees or bushes. In Custer County, Colorado, I find it breeding on the ground, sometimes at the very edge of creeks, in places where arboreal nests might have been made, and also better concealed ones. Captain C. E. Bendire, who inclines to the opinion that this bird breeds diversely in all parts of its range, where opportunities offer, writes (*in litt.*):—"I have found them nesting abundantly both on the ground and in bushes in the same locality and close together in Oregon. One thing struck me as peculiar: the nests when placed on the ground were almost always to be found on the extreme edge of a creek bank, when they could have selected far more suitable places, better concealed ones at any rate, a few feet away from the bank." This selection of creek banks, noticed both in Colorado and in Oregon, is remarkable. It had occurred to me that in Colorado the habit might have been formed to lessen the risk of being trampled upon by the herds of buffalo which used to inhabit this region, but Captain Bendire tells me the habit is observed also in regions where there never were any buffalo, which throws doubt upon my explanation.

Captain Bendire, who has so excellent a knowledge of the nesting-habits of American birds, kindly gives me a few notes on the subject, which it may be permissible to quote.

"Birds in the selection of their nesting-sites will adapt themselves to circumstances, as is well known, but as in the case just mentioned [*Scolecophagus*] it is hard to arrive at an entirely satisfactory conclusion. It is, for instance, easy to account for, why the *Archibuteo ferrugineus* should breed on the ground in Dakota, in many cases at any rate, and why *Falco peregrinus anatum* in trees in Kansas, but there are a number of other such departures from the old established rules, which cannot be so easily accounted for" (C. E. Bendire, *in litt.*, January 21, 1890).

Captain Bendire also cites *Buteo swainsoni* and *Archibuteo ferrugineus* as birds which sometimes nest on the ground in places where there is plenty of suitable timber, which one might have expected them to make use of.

These variations in habit are certainly puzzling: probably the important factors in deciding the terrestrial or arboreal nesting-habits of a bird are four:—

(1) *Ability to build arboreal nests.*—If this varied in a locality where arboreal nests were not greatly preferable to terrestrial ones, we can see how a minority of clever birds might build in trees, and a majority of duffers on the ground. The slight disadvantage to the ground-builders might be counterbalanced by their numbers.

(2) *Danger of falling.*—In regions where the trees are not suitable for holding nests, or where very high winds prevail, a terrestrial nest might be preferable; though the same species in another part of its range might do well to build arboreally.

(3) *Dangers of nesting on the ground.*—Such dangers would arise from terrestrial enemies, floods, &c., and would vary greatly no doubt in different regions. Where things were otherwise fairly balanced, a slight difference in this respect might decide the nesting of a bird.

(4) *Means of defence.*—Some birds, with special means of defence or of escaping observation, might build on the ground where others would take to trees.

T. D. A. COCKERELL.

West Cliff, Custer Co., Colorado.

Russian Transliteration.

I AM afraid the authors of the "new system" of transliteration have misunderstood my letter in yours of April 10 (p. 534), advocating "the tabulation of the system of transliteration which has been so long in use in this country" in preference to the adoption of the unnecessary novelties they propose to introduce. By the "system in use" I meant that for transliteration from Russian into *English*, and certainly did not include the transliterations from Russian into *German* which have been copied from books or memoirs in that language into English catalogues or journals. As practically all the examples the authors adduce in defence of their "new system," including both the atlases and the works with which they associate my name, are of this kind—*i.e.* merely copies of transliterations from Russian into *German*—I fail to see what bearing they have on the question of transliteration into *English*, however useful they might be in constructing a system for transliteration from Russian into German.

Another misapprehension is, they seem to imagine that I have propounded a system of transliteration of my own. I sincerely hope I shall never be guilty of doing anything so rash. I merely offered some friendly criticisms on the new system which the authors had devised, and I may supplement my remarks by here giving in tabular form the principal points in which this system differs from that which I conceive to be the English use:—

	English Use.	New System.
в	*v*	*v*
въ	*ff*	*v*
г	*h* before *e* or *i*, otherwise *g*	*gh*
ж	*j*	*zh*
кс	*x*	*ks*
у	*ou*	*u*
х	*ch*	*kh*
ч	*tch*	*ch*
щ	*shtch*	*shch*
ѣ	*é*	*ye*
ы	*y*	*ui*
ю	*u*	*yu*

I have already given a few examples of names which look uncouth when transliterated according to the new system, and I here add one more. It is

SKRZHIPSKIĬ.

When I wrote it down and observed its hieroglyphic appearance, there arose somehow in my mind a vision of a new system of chemical nomenclature devised many years ago by Laurent,

and his proposal to give to "alum" the name *atolan-telmin-ajafin-weso*. CHARLES E. GROVES.

Chemical Society, April 14.

P.S.—I need scarcely say how cordially I concur with Mr. W. F. Kirby's exceedingly apposite remark that no system of transliteration should be adopted offhand without full discussion.

WITH reference to the scheme of Russian transliteration propounded on p. 397 of NATURE (vol. xli.), I should be obliged if the editor of NATURE would allow me the opportunity of suggesting that different principles of respelling foreign languages in English might possibly be adopted with advantage for different purposes. The scheme referred to is one of strict transliteration; in other words, the aim is to represent the letters of a foreign alphabet uniformly by the same letters or combinations of letters in the English alphabet. For the purpose of drawing up lists of titles of books and papers in a foreign language—the purpose obviously kept in view by the propounders of the new Russian scheme—this principle is no doubt the best. It is the only one that makes it easy to consult a Russian dictionary. But it does not follow that the principle of strict transliteration is the best to adopt for foreign proper names occurring in a language different from that to which they belong. The third of the rules adopted by the Council of the Royal Geographical Society for geographical orthography is as follows: "The true sound of the word as locally pronounced will be taken as the basis of the spelling" (Proc. Roy. Geog. Soc., 1885, p. 535). This rule is inconsistent with any scheme of strict transliteration. I can imagine that two views may be held as to its propriety. Unquestionably there are difficulties in applying it, but surely for the purpose for which the rule was adopted it is at least defensible and worthy of serious discussion.

Even if it should be recognized, however, that it is desirable that one principle of conversion into a foreign alphabet should be adopted for one purpose, another for another, it will, I think, be generally admitted to be a matter of the greatest importance that an agreement should be come to among all concerned in such conversions as to those points which might be held in common on either system of conversion. All schemes of transliteration in the strict sense of the term are based on phonetic rules. The aim in all is to render the letters of one alphabet by the letters and signs most appropriately representing their normal sounds in another. It is the departures from the normal sounds that are disregarded. Now a uniform system of representing sounds, so far as it is at all desirable to represent foreign sounds in English, if devised with sufficiently wide regard to the requirements of different languages, would be of great use as a system to be followed for every word or name on the principle of phonetic respelling and to be adopted as the basis of every scheme of transliteration. GEO. G. CHISHOLM.

April 22.

On some Decomposed Flints from Southbourne-on-Sea.

THE curiously decomposed flint-pebbles which occur in the cliffs between Boscombe and Southbourne-on-Sea have not, so far as I have been able to ascertain, yet received the attention they deserve, and, with a view of obtaining other opinions before the completion of a paper on the subject, I venture briefly to offer mine.

I will not now deal generally with all the pebbles in the horizon alluded to, but specifically with some of unusual interest which occur at a certain point in the cliff, as these represent an extreme type of decomposition to which most of the less-altered pebbles may be found gradating. These type-pebbles occur in the cliff a short distance to the east of the pier at Southbourne-on-Sea, and present all the characteristic features of a littoral deposit.

A section of the cliff at this point shows:—

Blown sand	8 feet.
Brown loam, passing down into lighter-coloured sandy gravel containing angular and sub-angular yellow and brown flints without any definite mode of deposition	14 feet.

At the base of this, and resting on pure quartzose sand, free from flints, is a definite and more or less horizontal layer of rounded and decomposed flint-pebbles of about one pebble in thickness, partially embedded in the white sand on which they rest, and covered by the clastic matter of the bed above.

While some of these pebbles are apparently unaffected, most of them are eroded in a remarkable manner, having large portions of their substance removed; and others, though retaining their original form, are completely changed throughout their mass into a soft, white substance (crystalline silica) macroscopically like chalk, and as easily cut or sawn through. The largest wholly-decomposed specimen I have been able to procure measures 14 inches around its greatest circumference.

It is remarkable that these flint-wrecks preserve their original form and detail to such a degree of perfection that in most cases the soft surfaces retain the crescentic markings (mastoid) of incipient conchoidal fracture which resulted originally from the percussion due to wave-action.

As far as I am at present able to judge, the silica originally composing these pebbles was of two distinct kinds—a bluish-black, or more stable form (superior crystalline development), and a light-coloured, or less stable form (inferior crystalline development); for, in the specimens I have procured, the bluish-black variety does not appear to be abnormally affected, while the lighter-coloured variety is nearly always partially or completely decomposed. The wholly-decomposed pebbles would, therefore, have been formed of the unstable variety, while those eroded only would have been formed of a combination of the two, the stable portion now remaining.

My supposition seems to be strengthened by the evidence obtained from the banded flints, which are very plentiful here. These banded flints are formed of alternating zones of the two varieties, and in many cases the unstable form has been so decomposed as to leave only successive zones of the more stable form fitting loosely one into the other like a nest of boxes, and as easily separable. Notwithstanding this fact these unstable zones—before decomposition—are apparently as well able to withstand *mechanical* erosion as the stable zones, a conclusion arrived at through having some of these banded flints subjected to the action of the sand-blast for 15 minutes without any "ridging" taking place.

That the decomposition of these particular flint-pebbles must have taken place prior to the deposition of the superincumbent bed of clastic material is proved, I think, by the fact that none of the flints composing this bed appear to be decomposed, even the smallest chips being comparatively unaffected.

From this and other facts observed, I gather that the decomposition of these pebbles must have taken place when they were exposed to the air, but I do not think atmospheric influences alone would be sufficient to account for the evident rapidity and effectiveness of the process; we must seek a special cause for an unusual effect.

I venture to suggest that the solvent which has in this case removed the colloidal silica was derived from decaying sea-weed, and other organic matter, cast up from time to time by the waves upon this (then) pebbly beach. Large masses of sea-weed cast up by storm-waves take a considerable time to decompose, and during such period is it not possible that they might produce alkaline solutions, or—as has been suggested to me by Dr. Irving—combinations of ammonia and organic acids? Either of these is a well-known solvent of colloidal silica. The action of such solvents might have been accelerated by the mechanical process through which most of these pebbles passed prior to their final state of rest, viz. the action of the sea-waves in producing the mastoid structure already alluded to, this molecular disruption no doubt facilitating the penetration of the solvent to the very heart of the pebble. It is worthy of note, too, that in some of the eroded specimens procured, the remaining unaffected parts are almost entirely free from these incipient fractures, a fact which—if we ignore the supposed variation in the stability of the silica—suggests the necessity for a combination of the chemical and mechanical causes to produce the effects observed.

I have dealt here with a special case only, in the hope that my suggestions may be found applicable to the many in which we see abnormal decomposition occurring in the flint-pebbles of littoral deposits, and which appears to be distinct from the "weathering" so frequently seen occurring to considerable depths in the exposed flints of deposits other than littoral.

Bournemouth, April 16. CECIL CARUS-WILSON.

Doppler's Principle.

As a student I should be much obliged to any reader for an explanation of the following difficulty. In considering Doppler's

principle as applied in acoustics, we find four cases: (1) approach of observer, source and medium being at rest; (2) recession of observer, source and medium at rest; (3) approach of source, observer and medium at rest; (4) recession of source, observer and medium at rest.

I have consulted all the standard authorities which have occurred to me, and find they all agree in the 1st and 2nd cases. In (3), Doppler, Lord Rayleigh, Prof. Everett (1st method in "Deschanel"), Jamin, and Ganot have the same result as in (1). Lord Rayleigh in his "Theory of Sound," vol. ii. p. 142, says, "In the case of a periodic disturbance a velocity of approach v is equivalent to an increase of frequency in the ratio $a : a + v$," a being the velocity of sound. In another place the same author says that it is the *relative* velocity of source and observer alone that is important. The above-mentioned authorities appear to hold the same views.

But Prof. Everett has a more rigorous demonstration than the above, which leads to the result—old pitch : new pitch :: $a - v : a$. This result is the same as that given by Mach, "Ton u. Färberänderung durch Bewegung" (1874), and as that used by Balfour Stewart, "Treatise on Heat."

In the 4th case the first-mentioned authors again agree, giving as a result—new pitch : old pitch :: $a : a - v$. Prof. Everett's and E. Mach's results agree in giving $a + v : a$ as the ratio.

It will be readily admitted that the first two cases are simpler problems to attack than the last two. The results of the minority for the cases (3) and (4) seem to me to come from looking at the change in wave-length first, those of the majority from taking into account the number of waves met by the observer. In any case the disagreement among such authorities is naturally beyond me to explain. The motion of the medium does not appear to offer any special difficulty.

G. H. Wyatt.

The Relative Prevalence of North-east and South-west Winds.

The direction of the wind has been noted twice daily at this Observatory (9 a.m. and 9 p.m.) during the past 6 years, with the following mean results:—

N.	N.E.	E.	S.E.	S.	S.W.	W.	N.W.	Calm.
56	48	30	25	23	65	45	60	13

The period under consideration is not sufficiently long to make the series of observations of any great value, but as Mr. Ellis asks for comparisons, I am happy to give them for what they are worth.

C. E. Peek.

Rousdon Observatory, Lyme Regis, April 26.

The London Mathematical Society's List of Papers.

In Nature (vol. xli. p. 594) it is stated that "a complete index of the papers printed in the Proceedings of the London Mathematical Society has been issued." It will be in the recollection of some that a previous issue of the Index to the papers contained in the first 17 volumes was announced in Nature (vol. xxxvi. p. 42): it is a re-issue of this list completed for the first 20 volumes that is now noted. The former edition of 3000 copies was soon dispersed, and resulted in warm expressions of thanks from mathematicians, and also in an increased sale of the Proceedings. If other Societies would, in like manner, issue lists of the titles of papers printed in their Proceedings, they would no doubt meet with a like reward. All mathematicians, and others who are interested in mathematical research, can have a copy on application to the Secretaries (22 Albemarle Street, W.), or to the publisher (Francis Hodgson, 89 Farringdon Street, E.C.).

April 26. R. Tucker, Hon. Sec.

THE UNITED STATES SCIENTIFIC EXPEDITION TO WEST AFRICA, 1889.

As the work of the Expedition approaches conclusion, I venture to hope that a brief partial recital of results may be worth notice in Nature, particularly as, in many of the ports we have visited, English courtesy and English hospitality have contributed in large measure to the facilities for prosecuting our work, not to say also very greatly to the delight of doing it.

I find it a trifle difficult to say just where to begin, but Dr. David Gill, H.M. Astronomer at the Cape, comes first to mind, and surely no one could have devoted himself more unsparingly to the interests of the Expedition than he did during our stay of a fortnight and more at Cape Town: and through his liberal provision for every requirement of the observers, it became possible to swing the pendulums in the Royal Observatory buildings, the same spot occupied in previous gravity-research at the Cape. Had it been expedient to delay the *Pensacola* longer, Dr. Gill's suggestion would gladly have been acted upon, and an additional gravity-determination made at the Kimberley diamond fields, 650 miles in the interior, at an elevation of about 4000 feet; but there was time only for members of the Expedition not engaged in exact measures to proceed as far inland as that; and the movements and operations of the naturalists and others who desired to visit the Cape Colony country as far as Kimberley became feasible through the kind offers of Mr. Difford, the Secretary of the Colonial Government Railways.

Not only at Cape Town had we much occasion to thank His Excellency Sir H. B. Lock, the Governor of the Colony, but two months later, at Ascension Island, through his courteous intervention, and the obliging civilities of Admiral Wells, R.N., all possible preparation had been made; while, on our arrival, Captain Napier, R.N., in charge of Ascension, most thoughtfully smoothed the way by arranging to our entire satisfaction all matters which could in any way facilitate the work we had planned for that interesting island.

Nor am I forgetting the multitude of courtesies at the hands of Governor Antrobus of St. Helena, where all desired assistance was afforded, and where work similar to that at Ascension was undertaken and completed.

In this connection, I must not omit mention of the American Navy, for neither the Expedition in its present form nor its work could have become an accomplished fact but for the enlightened policy of Secretary Tracy, who assigned a man-of-war for its transport to Africa and home again; of Admiral Walker, and later, Commodore Dewey, Chiefs of Naval Bureaux, who devoted their energies ungrudgingly to the regulation of all matters official affecting the welfare of the Expedition; and of Captain Yates, the commander of the U.S.S. *Pensacola*, who has done everything in his power to forward the prosecution of the scientific work.

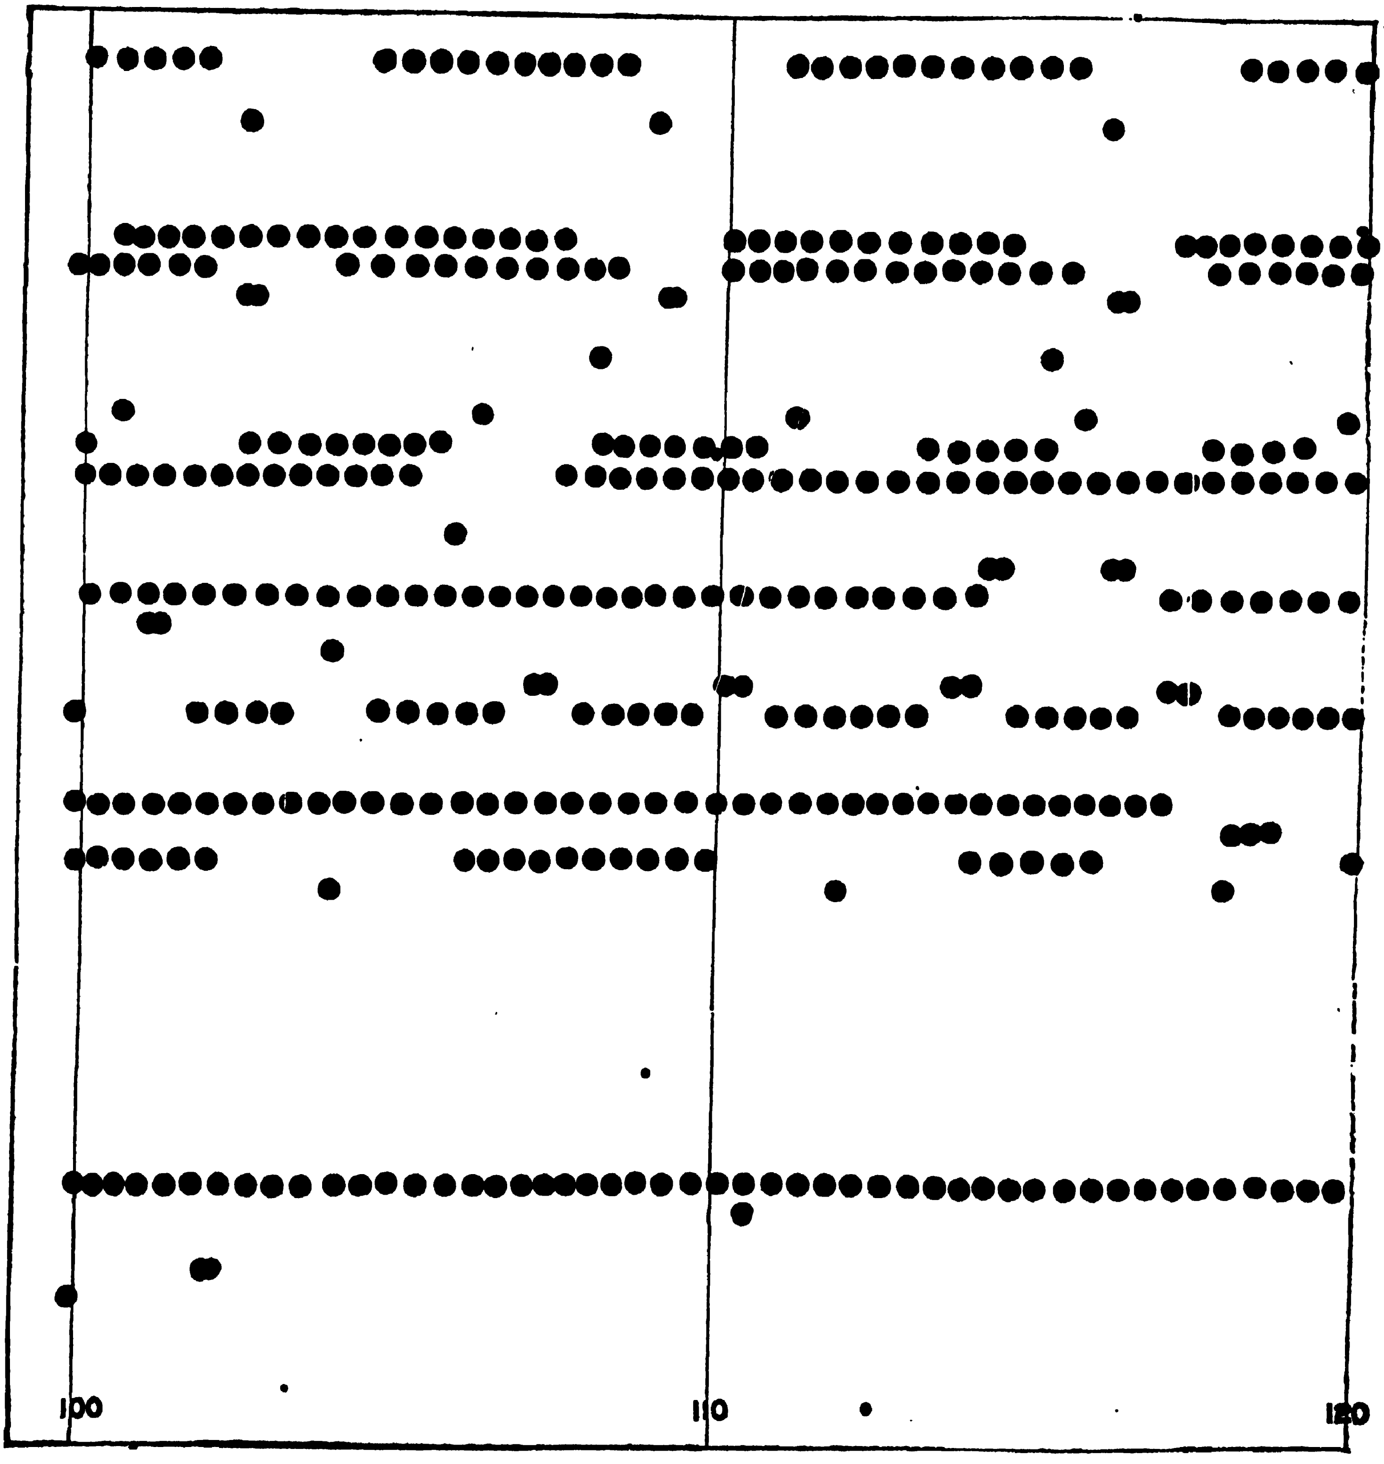
The *Pensacola* left New York on October 16 last; called at the ports of Horta, Fayal, Azores, November 2-3; San Vicenti, Cape Verdes, November 10-12; St. George's Parish, Sierra Leone, November 18-20; Elmina, Gold Coast, November 26-28; São Paolo di Loanda, December 6-7; Eclipse Bay, Cape Ledo, December 8-27; again at Loanda, December 28-January 6; Cape Town, January 17-February 6; St. Helena, February 20-March 10; and arrived at Ascension six days later, which port she will probably leave about April 10.

Now to some of the results.

At all these stations except Cape Ledo, the magnetic elements have been carefully investigated by Mr. Preston, of the U.S. Coast and Geodetic Survey. Also he had an additional magnetic station at Cabiri, about 45 miles interior from Loanda, whither he went for the immediate eclipse period.

The short time available before the eclipse made it impracticable to begin the gravity-determinations until Loanda; there Mr. Preston swung the Peirce pendulums, and again at the Royal Observatory, Cape Town. At St. Helena two complete swings were obtained, the one at a sea-level station near the Castle, Jamestown, and the other at Longwood, elevation 1750 feet. It was not

thought practicable to re-occupy Foster's station at Lemon Valley. Here at Ascension the sea-level station at Garrison is already complete; and, as I write, Mr. Preston and Prof. Bigelow are taking quarters near the summit of Green Mountain for the second station, near the spot occupied by Foster sixty years ago, elevation between two and three thousand feet. Auxiliary magnetic work is undertaken at both these upper-level island stations. Between Ascension and New York but one prolonged stop is at present contemplated—at Bridgetown, Barbados—where magnetics will be done, and gravity-work, if practicable. Also, Bermudas may be included, but that is perhaps unlikely. In addition to the bearing of this work on terrestrial physics and geologic theories, it is worthy of note, in passing, that all these stations, including Washington, where swings are made both before the departure of the Expedition and after its return, lie within a narrow great-circle belt, which can at



Control-sheet of the Pneumatic Commutator between the 100th and 120th seconds of Totality.

any time be continued on through the United States and Canadas and Alaska, forming an extraordinary stretch of gravimetric survey.

Regarding the eclipse and the stay of the astronomers at Cape Ledo, it has to be said, to our great regret, that the direct photo-heliograph of 40 feet focal length was the only instrument with which eclipse-records could be secured. These were photographs of the partial phases, over 100 in number, obtained between clouds. The instrument was built under the immediate supervision of Prof. Bigelow, and has, among other peculiarities, a skeleton tripod-mounting which will be fully figured in the definitive report of the Expedition. It has been proven practicable to dispense with the heliostat mirror, always the weak point in the horizontal photo-heliograph; and to manipulate readily a camera long enough to produce a 4½-inch solar image direct: and this, too, by means of a mounting easy to transport and to set in position. The photographs were taken in groups of ten, on circular plates of 22 inches diameter. The apparatus auxiliary

to these rotating plates made the whole automatic, the driving power being compressed air under electric control. A form of sand-clock was found most efficient for counteracting the diurnal motion.

For the total phase our preparations were even more elaborate. What I attempted was nothing short of the complete automatic operation of all the photographic instruments, whether photometers, spectroscopes, cameras, or polariscopes. Over a score of these instruments were securely adjusted upon an immense polar axis, split, and mounted on the English plan. Powerful clock-work with a Repsold governor carried the whole with great accuracy. All such mechanical movements were specially invented and constructed as were necessary to work the exposing-shutters, to change exposed plates for fresh ones, and to perform all other operations, as rotating Nicols, varying apertures of objectives, trailing plates, and the like. Each movement, of whatever sort, took place as a result of the thrust of a small, collapsible, pneumatic bellows. The precise instants of collapse of these bellows were controlled through the intervention of the Gally pneumatic valve, a most ingenious device whereby any required number of very small air-currents (exhaust) are made to control the motion of an equal number of large air-currents (also exhaust). This principle has been very successfully employed in the automatic playing of musical instruments, and anyone familiar with the modern forms of these, in which a perforated paper sheet takes the place of the music, will readily comprehend how the whole thing was done. In the pneumatic commutator actually used at the African station forty-eight half-inch currents were under absolute control of a small paper sheet, about nine inches wide, suitably perforated, and unwinding at an invariable rate from a chronograph barrel. Thence it passed over the series of minute apertures through which flowed the lesser exhaust-currents, each of which controlled the action of its own valve, and consequently of its appropriate large exhaust-current, through suitable pipes leading to the individual pneumatic bellows. A portion of the commutator-sheet is represented in the illustration.

I do not need to specify here the detail of astronomical apparatus which this pneumatic commutator operated; but in the collection of totality-instruments were two 8-inch silver-on-glass mirrors, four spectroscopes, and a variety of objectives for a variety of purposes, ranging all the way from a ¾-inch aperture in one of the polariscopes to the Harvard 8-inch doublet of 13 feet focal length. The whole number of plates, or separate exposures, was in excess of 300, totality being 190 seconds in duration; and when once started, the whole affair looked out for itself absolutely, so long as the necessary power was supplied at the main exhaust-bellows.

But totality was completely clouded under; and instead of a fine accumulation of photographic data, I have only the gratification of having shown it to be practicable in the future for one eclipse observer to operate an indefinite amount of photographic apparatus quite as readily as, and with greater certainty than, he would have attended to only two or three cameras by hand heretofore. In converging all this apparatus toward readiness for eclipse-day, I had of course much valued assistance, which will be fully acknowledged elsewhere; and I need only mention here Prof. Bigelow, Mr. Davis, and Mr. Van Guysling, who were specially helpful in devising required movements and practically constructing them.

The totality-area in West Africa appears to have been unusually overcast. Auxiliary observers at Cabiri had clouds; at Cunga, clouds; at Dondo, clouds; while at Cazengo, Oeiras, Muxima, Kakulu, and Bom-Jesus it was cloudy too. Also, about 15 miles out at sea, in the path of central eclipse, whither the *Pensacola* had gone in the hope of additional results, the sky-conditions were perhaps slightly better, but still so bad that it is doubtful whether the true corona was seen at all.

Lest I weary anyone who may be reading this with too long a statement of our work, I omit here all account of the natural history of the Expedition, only saying for the present that Messrs. Brown, sent out by the U.S. National Museum, have been actively engaged in collecting at all the ports made by the *Pensacola*, and their materials will, I dare say, be competently discussed on the return of the Expedition. More about this later. At Ascension, opportunity for trawling is now for the first time available, and so far with fair success. While the main eclipse party was established at Cape Ledo, naturalists and anthropologists were in the interior about three weeks, at Cunga and at Dondo, His Excellency the Governor of Loanda, and the Directors of the Caminho de Ferro Trans-Africano, having courteously afforded them every facility for the prosecution of their work there. Physical measurements were taken among the Umbundus, Cabindas, Bailundas, Quissamas, and others; collections of folk-lore, fetishes, and mind-products made; and general information gathered concerning a variety of subjects indicated in the manual of the Anthropological Society of Great Britain. On reaching the Cape, both naturalist and anthropologist found the outlook so promising that they applied for discharge from the Expedition there, in order to continue their work in the Cape peninsula. The opportunities were indeed rare: a great exploring Expedition was about organizing, under the auspices of the English Syndicate, to which the King of the Matabele has granted unusual privileges and concessions, in a region for the most part untravelled by white men, and represented as very rich in material for natural history and other research. The Expedition is particularly indebted to the Rev. G. H. R. Fisk, of Cape Town, for a very valuable collection of tortoises, embracing *Testudo pardalis*, *T. angulata*, *T. trimeni*, and *T. tentoria*; *Homopus areolatus*, *H. femoralis*, and *H. signatus*, the representatives of these latter forming a perfect series of the South African *Homopus*.

The progress of M. Heli Chatelain's researches in the West African tongues is gratifying, and bids fair to constitute a valuable section of the work of the Expedition. He remains in Angola for some months yet, to gather linguistic material for various works he has in hand—among them his "Grundzüge des Ki-mbundu," in which the elements of this language are compared with those of Kixi-kongo, Luba, Lunda, N-mbundu, Oshi-ndonga, and Otyi-herero. The results will enable one to form an idea of the mutual relations of the languages of Central West Africa.

I may say here that Prof. Bigelow, in addition to assisting in the pendulum-work at St. Helena and Ascension, has been diligently engaged upon theoretic researches on the corona and terrestrial magnetism, the beginnings of which are outlined in his paper already published by the Smithsonian Institution. As yet he inclines to speak of this work with much reserve; but if the key to the solution of these complex phenomena has not actually been found, it surely looks strongly that way. By Dr. Gill's kindness, the resources of the excellent library of the Cape Observatory were freely and gladly drawn upon in this work.

Of the Bulletins, or preliminary publications of the Expedition, thirteen are already issued—one each relating to general matters, to terrestrial physics, to philology, and to localities of scientific interest in St. Helena; two to meteorology and to natural history; and five to the total eclipse.

I reserve for another occasion all account of the important researches which Prof. Cleveland Abbe, Meteorologist of the Expedition, has been sedulously prosecuting for the past five months and over, with improved means, and under rare conditions at sea and on land.

DAVID P. TODD.

U.S.S. *Pensacola*, Ascension, March 27.

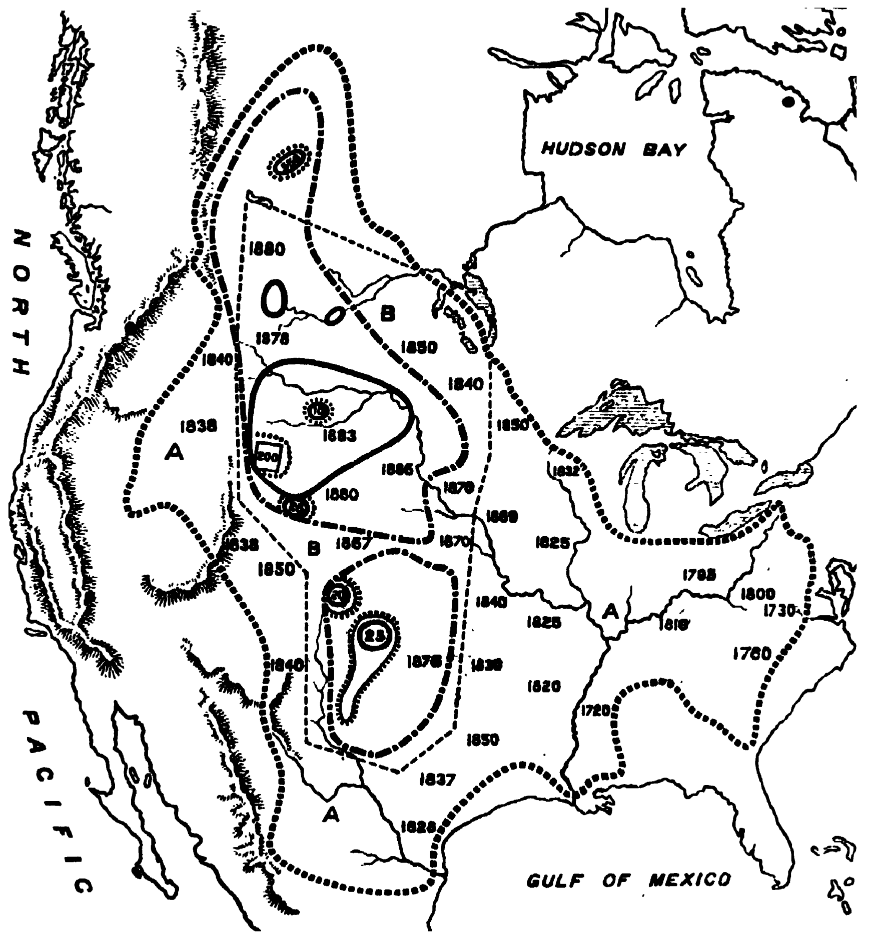
THE EXTERMINATION OF THE AMERICAN BISON.[1]

In the whole course of the history of man's relations with the lower animals, no sadder chapter will ever be written than that which tells of the practical extinction of the bison, which, only a short twenty years since, wandered in countless thousands over the vast prairies of the northern half of the American continent. This mournful story—mournful alike to the naturalist, to the sportsman, and to the trader—the author of this memoir recounts in such a full and lucid manner as to have practically exhausted the subject. Indeed, this memoir, in conjunction with Mr. J. A. Allen's monograph of the recent and extinct American bisons, does all that can be done in the way of literature to atone for the loss of the animal itself as a feature of the North American continent.

The memoir before us—which, we should say, is issued as a separate volume—is divided into three parts. The first of these deals with the life-history of the bison, the second with its extermination, while the third gives the history of the Expedition despatched by the Smithsonian Institution, in 1886, to procure specimens for the National Museum before it became too late. Of this Expedition the author was a prominent member, and the results of his labours are now exhibited in the magnificent case of stuffed specimens set up by his own hands in the National Museum at Washington. An excellent illustration of this group is given in the frontispiece to the volume.

After briefly alluding to the earliest records of a knowledge of the existence of the American bison by Europeans, Mr. Hornaday proceeds to notice its geographical distribution. In illustration of this important part of the subject a map is given, showing not only the original distributional area, but also the division by the Union Pacific Railway into the great northern and southern herds, and the gradual contraction and isolation of their areas, finally ending in the few spots where scattered individuals still linger on. For the benefit of our readers we give a reduced reproduction of that portion of this map comprising the bison area. Our author states that the bison originally ranged over about one-third of the entire North American continent. Thus, "Starting almost at tide-water on the Atlantic coast, it extended westward through a vast tract of dense forest, across the Alleghany Mountain system to the prairies along the Mississippi, and southward to the delta of that great system. Although the great plain country of the West was the natural home of the species, where it flourished most abundantly, it also wandered south across Texas to the burning plains of North-Eastern Mexico, westward across the Rocky Mountains into New Mexico, Utah, and Idaho, and northward across a vast treeless waste to the bleak and inhospitable shores of the Great Slave Lake itself."

About a century and a half ago, when the greater part of North America was still an unknown region to the white races, it would appear that the bison had about attained its maximum development; and the author suggests that if it had been left undisturbed it would probably have crossed the Sierra Nevada and the Coast Range to reach the fertile plains of the Pacific slope. This enormous range would also in course of time have probably given rise to local races, of which there is an actual example in the so-called "wood-" or "mountain-buffalo"; and in the opinion of the author it is probable, if things had been left to themselves, that, while the bisons in the neighbourhood of the Great Slave Lake would have developed an extra amount of hair, and thus tended to resemble the musk-ox of the Arctic regions, those in the warm regions of the south would tend to lose their hair, and attain a condition resembling that of the Cape buffalo and the Indian gaur. The appearance of the white man on the scene soon, however, put a stop to Nature's processes.



Boundary of the area once inhabited by the bison.

Approximate boundary between the area of desultory extirpation (A) and that of systematic destruction for robes and hides (B).

Range of the two great herds in 1870.

Range of the herds in 1880.

Range of the scattered survivors of the southern herd in 1875, after the great slaughter of 1870–73.

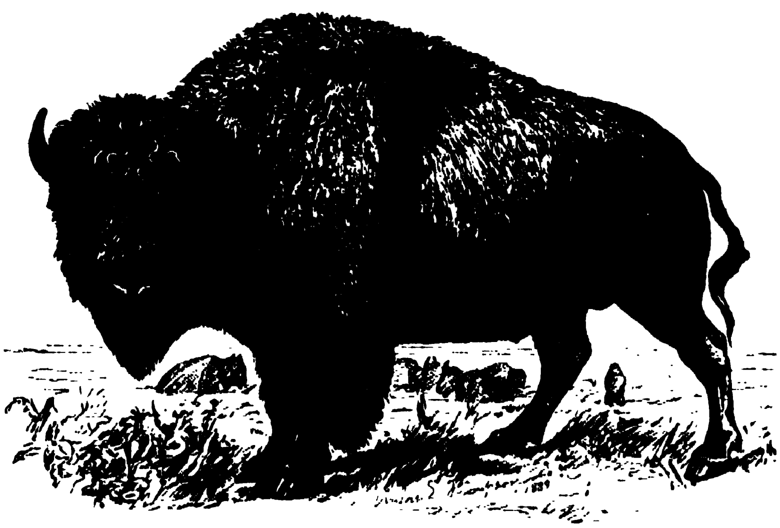
Range of the northern herd in 1884, after the great slaughter of 1880–83.

The third section of the first part is devoted to the consideration of the former numerical abundance of the bison. Here the author considers that the current accounts of the extraordinary number of these animals are not in the least exaggerated. Thus he observes that "it would have been as easy to count or to estimate the number of leaves in a forest as to calculate the number of buffaloes [the author frequently employs this American misnomer for the bison] living at any given time during the history of the species previous to 1870. Even in South Central Africa, which has been exceedingly prolific in great herds of game, it is probable that all its quadrupeds taken together on an equal area would never have

[1] "The Extermination of the American Bison." By W. T. Hornday. From the Report of the U.S. National Museum for 1886–87. Pp. 369–548, Pls. j.–xxii. (Washington: Government Printing Office, 1889.)

more than equalled the total number of buffalo in this country forty years ago." As an instance of these enormous numbers, it appears that, in the early part of the year 1871, Colonel R. I. Dodge, when passing through the great herd on the Arkansas, and reckoning that there were some fifteen or twenty individuals to the acre, states from his own observations that it was not less than 25 miles wide and 50 miles deep. This, however, was the last of the great herds; and Mr. Hornaday estimates that the number of individuals comprising it could not be reckoned as less than four millions. Many writers at and about the date mentioned speak of the plains being absolutely black with bison as far as the eye could reach; and Mr. W. Blackmore tells of passing through a herd for a distance of upwards of 120 miles right on end, in travelling on the Kansas Pacific Railroad. Frequently, indeed, trains on that line were derailed in attempting to pass through herds of bison, until the drivers learned that it was advisable to bring their engines to a standstill when they found the line blocked in this manner. Plate III. gives a graphic illustration of a train halted as it reaches the border of a herd of bison.

In the fourth section of the part under notice, we have a full description of the general characters of the American bison, and the points by which it is distinguished from its European congener, the Lithuanian aurochs. In this connection we reproduce,



Bull Bison in the National Museum at Washington.

on a smaller scale, the author's figure of the bull bison mounted in the United States National Museum, since he tells us that many of the figures to be met with do not give by any means a fair idea of the grand proportions of the animal, being taken either from domesticated or from badly-mounted specimens. The height of this bull is upwards of 5 feet 8 inches at the withers. The author remarks, however, that the specimens obtained by the Smithsonian Expedition were above the average height, since they were the fleetest and strongest examples of the race, which had escaped from the slaughter of the great herds by their endurance and speed. It is also remarked that these bison were of extreme muscular development, and showed no traces of the large amount of fat so characteristic of the members of the great herds when they were comparatively undisturbed upon the open plains.

The following sections treat of the habits, food, and disposition of the bison—subjects into which we need not enter on this occasion. In the eighth section we have a full discussion as to the economic value of the bison, in the course of which it is shown what a severe financial loss the States have sustained in permitting its extermination. Some very interesting observations then follow as to the number of herds or individuals of bison—either pure or half-bred—now existing in captivity in various parts of the States, and in other countries. From this it appears that on January 1, 1889, there were 256 pure-bred specimens known to be kept in captivity; while the herd of wild ones, protected by the United States Government in the Yellowstone National Park, numbered about 200.

With the second and most interesting part we come to the proper subject of the memoir—the actual extermination of the bison. The primary cause which has led to this sad result is, of course, the spread of civilization—and more especially railways—over the area formerly sacred to the bison and a few Indians. But as secondary causes the author mentions the utterly wanton and reckless way in which the unfortunate animals were shot down for the sake merely of their hides or tongues; the want of protective legislation on the part of the Government; the preference for the flesh and skin of cows; the marvellous stupidity and indifference to man of the animals themselves; and the perfection of modern fire-arms.

Among the methods of slaughter the so-called "still-hunt," where the hunter creeps up to a herd and shoots one after another of its members, appears to be one of the most deadly, owing to the crass stupidity of the animals themselves. The plan adopted was first to shoot the leader, when the remainder would come and stupidly smell round the body, till another animal assumed the post of leader, and was shot down when it was about to make a move; the same process being repeated almost without end. Riding down, surrounding, impounding, or hunting in snow-shoes, were, however, other equally effective methods of destruction.

It is stated that, in spite of the merciless war which had been in a desultory manner incessantly waged against the bison, both by whites and Indians, for over a century, and the consequent gradual restriction of its area, it is certain that there were several million head alive as late as 1870. The period of desultory destruction may be roughly reckoned as extending from 1730 to 1830. During that time the bison had been completely driven away from the Eastern United States, and also from the districts lying to the west of the Rockies (where it had never been very numerous); and the area had thus become practically restricted to that inclosed by the broken line on the map.

From 1830 to 1888 is reckoned as the period of organized and systematic slaughter for the sake of the skin and flesh; and the author does not measure the terms he employs with reference to the supineness of the Government during this period. He gives a detailed account of the various expeditions which were steadily playing upon the great herd occupying the area indicated on the map; and the gradually increasing demand for "buffalo-robes." The real beginning of the end was, however, the completion in 1869 of the Union Pacific Railway, which completely cut the bison area in twain, and divided the great herd into a southern and a northern moiety.

The history of the southern herd is very short. Its central point was somewhere about the site of the present Garden City in Kansas; and although its area was much less than that occupied by the northern herd, it probably contained twice as many animals, the estimated number of individuals in 1871 being not less than three millions, and probably nearer four. The completion of the Kansas branch of the Union Pacific in 1871, which ran right through the head-quarters of the southern herd, was the immediate cause of its destruction; and we are told that the chief slaughter, which began in 1871, attained its height in 1873. So wanton and wasteful, indeed, was the destruction during this period that it is said that every single hide sent to market represented four individuals slain; and the description given by the author on p. 4[illegible] of the condition of the country owing to this frightful slaughter is almost sickening. The author observes that "it is making a safe estimate to say that probably no

fewer than 50,000 buffaloes have been killed for their tongues alone, and the most of these are undoubtedly chargeable against white men, who ought to have known better." Over three and a half million individuals are estimated to have been slaughtered in the southern herd between 1872 and 1874. In the latter year the hunters became alarmed at the great diminution in the number of the bison, and by the end of 1875 the great southern herd had ceased to exist as a body. The main body of the survivors, some 10,000 strong, fled into the wilder parts of Texas, where they have been gradually shot down, till a few years ago some two or three score remained as the sole survivors of the three or four millions of the great southern herd. Bison-hunting as a business definitely ceased in the south-west in 1880.

Almost equally brief, and equally decisive, is the history of the great northern herd. The estimated number in this herd in 1870 is roughly put at a million and a half, ranging over a much wider area than the southern herd. The portions of the herd in British North America appear to have been exterminated first. Previously to 1880, the Sioux Indians had made an enormous impression on the numbers of this herd in the States of Dakota and Wyoming; but the beginning of the final destruction of the herd may be said to date from that year, which was signalized by the opening of the Northern Pacific Railway, running right through their area. In that year the herd was hemmed in on three sides by Indians armed with breechloaders, who enormously reduced its numbers. A rising market for "buffalo-robes," in 1881, stimulated a rush on this herd, till "the hunting-season which began in October 1882 and ended in February 1883 finished the annihilation of the great northern herd, and left but a few small bands of stragglers, numbering only a very few thousand individuals all told." It was long thought that a large section of the herd was still surviving, and had escaped into British territory, but this proved to be a mistake.

"South of the Northern Pacific Railway, a band of about three hundred settled permanently in and around the Yellowstone National Park, but in a very short time every animal outside of the protected limits of the Park was killed; and whenever any of the Park buffaloes strayed beyond the boundary, they too were promptly killed for their heads and hides. At present the number remaining in the Park is believed by Captain Harris, the Superintendent, to be about two hundred, about one-third of which is due to the breeding in protected territory."

It is curious to notice that even the bison hunters themselves were unaware of the extinction of the northern herd in the spring of 1883; and costly expeditions were actually fitted out in the autumn of that year to arrive at the bison country and find that the "happy hunting-grounds" existed no longer.

Such very briefly is the mournful history of the extermination of the two great herds of American bison. Scattered individuals or small droves still exist here and there in the more secluded parts of the country, in addition to those preserved in the Yellowstone. The pursuit of them is, however, unremitting, and the author considers that the final disappearance of every unprotected individual is but a question of time. In 1889 some twenty bison were seen grazing in the Red Desert of Wyoming, which narrowly escaped destruction. We have already mentioned the survivors of the southern herd still lingering in Texas; but there is strong evidence of the existence in the British district of Athabasca of a herd of "wood-buffalo," estimated at upwards of 550 in number. Exclusive of those in the Yellowstone, the number of wild bison existing in the United States on January 1, 1889, is given as 85. Finally, the whole census of living examples of the American bison—both wild and tame—at the date mentioned, gives only 1091 individuals.

That the Government of the United States will do all they can to increase and preserve the herd in the Yellowstone Park goes without saying; but the warning of the author that without great care, and unless (if this be possible) crossed, they will gradually deteriorate in size, should not be overlooked.

The account of the Smithsonian Expedition into Montana, which forms the concluding portion of the volume, although well told, is not of sufficient general interest to need further notice here.

In conclusion, we have to congratulate the author on having brought together such a number of facts in relation to the extermination of the bison, which, if they had not been recorded while they were fresh in men's memories, would probably have been entirely lost.

R. L.

DICE FOR STATISTICAL EXPERIMENTS.

EVERY statistician wants now and then to test the practical value of some theoretical process, it may be of smoothing, or of interpolation, or of obtaining a measure of variability, or of making some particular deduction or inference. It happened not long ago, while both a friend and myself were trying to find appropriate series for one of the above purposes, that the same week brought me letters from two eminent statisticians asking if I knew of any such series suitable for their own respective and separate needs. The assurance of a real demand for such things induced me to work out a method for supplying it, which I have already used frequently, and finding it to be perfectly effective, take this opportunity of putting it on record.

The desideratum is a set of values taken at random out of a series that is known to conform strictly to the law of frequency of error, the probable error of any single value in the series being also accurately known. We have (1) to procure such a series, and (2) to take random values out of it in an expeditious way.

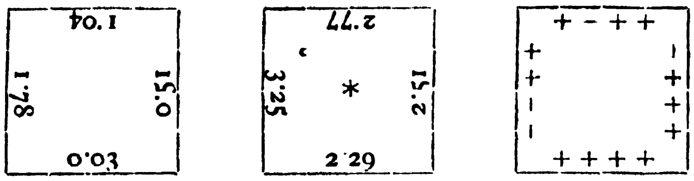
Suppose the axis of the curve of distribution (whose ordinates at 100 equidistant divisions are given in my "Natural Inheritance," p. 205) to be divided into n equal parts, and that a column is erected on each of these, of a $+$ or a $-$ height as the case may be, equal to the height of the ordinate at the middle of each part. Then the values of these heights will form a series that is strictly conformable to the law of frequency when n is infinite, and closely conformable when n is fairly large. Moreover the probable error of any one of these values irrespectively of its sign, is 1.

As an instrument for selecting at random, I have found nothing superior to dice. It is most tedious to shuffle cards thoroughly between each successive draw, and the method of mixing and stirring up marked balls in a bag is more tedious still. A teetotum or some form of roulette is preferable to these, but dice are better than all. When they are shaken and tossed in a basket, they hurtle so variously against one another and against the ribs of the basket-work that they tumble wildly about, and their positions at the outset afford no perceptible clue to what they will be after even a single good shake and toss. The chances afforded by a die are more various than are commonly supposed; there are 24 equal possibilities, and not only 6, because each face has four edges that may be utilized, as I shall show.

I use cubes of wood $1\frac{1}{4}$ inch in the side, for the dice. A carpenter first planed a bar of mahogany squarely and then sawed it into the cubes. Thin white paper is pasted over them to receive the writing. I use three sorts of dice, I., II., and III., whose faces are inscribed with the figures given in the corresponding tables. Each face contains the 4 entries in the same line of the table. The diagram shows the appearance of one face of each of the 3 sorts of dice; II. is distinguished from I. by an asterisk

in the middle; III. is unmistakable. It must, however, be understood, that although the values are given to the second place of decimals both in the tables and in this diagram, I do not enter more than one decimal on the dice. The use of the second decimal is to make multiplication more accurate, when a series is wanted in which each term has a larger probable error than 1.

I. II. III.



In calculating Table I., *n* was taken as 48. This gives 24 positive and 24 negative values in pairs, but I do not enter the signs on the dice, only the 24 values, leaving the signs to be afterwards determined by a throw of die III. It will be observed that the difference between the adjacent values in Table I. is small at first, and does not exceed 0·2 until the last three entries are reached. These, which are included in brackets, differ so widely as to require exceptional treatment. I therefore calculated Table II. on the principle of dividing that portion of the curve of distribution to which those entries apply, into 24 equal parts and entering the value of the ordinate at the middle of each of those parts in that table. Moreover, instead of entering the three bracketed values on die I. I leave blanks. Then whenever die I. is tossed and a blank is turned up, I know that I have to toss die II., and to enter the value shown by it.

The precise process I follow is to put 2 or 3 of dice I. into a small waste-paper basket, to toss and shake them, to take them out and arrange them on a table side by side in a row, squarely in front of me, but by the sense of touch alone. Then for the first time looking at them, to write down the values that front the eye. If, however, one of the blank spaces fronts me, I leave a blank space in the entries. Having obtained as many values as I want from die I., I fill up the blank spaces by the help of die II.

Lastly, the signs have to be added. Now as $24 = 16 + 8 = 2^4 + 2^3$, it follows that 16 of the edges of die III. may be inscribed with sequences of 4 signs in every possible combination, and the remaining 8 with sequences of 3 signs. Then when die III. is thrown, the several entries along its front edge, which are 4 or 3 in number as the case may be, are inserted in an equal number of successive lines, so as to stand before the values already obtained from the other dice.

The most effective equipment seems to be 3 of die I., 2 of die II., 1 of die III., making 6 dice in all.

Values for Die I.

FRANCIS GALTON.

THE ROYAL SOCIETY SELECTED CANDIDATES.

THE following fifteen candidates were selected on Thursday last (April 24) by the Council of the Royal Society to be recommended for election into the Society. The ballot will take place on June 5, at 4 p.m. We print with the name of each candidate the statement of his qualifications.

SIR BENJAMIN BAKER, Mem Inst. C.E.,

Hon. Mem. of the American Society of Mechanical Engineers, and of the Society of Engineers. Hon. Mem. of the Manchester Lit. and Phil. Soc. Has been engaged as an Engineer during the last twenty-five years, in the design and construction of many important works at home and abroad, including the Forth Bridge, and has carried out numerous investigations relating to the strength of materials and of engineering structures generally, and has contributed papers thereon to various Scientific Societies, viz., Proc. Inst. Civil Eng., Trans. Amer. Soc. Mech. Eng., Brit. Assoc. Reports, &c. Author of "A Theoretical Investigation into the Most Advantageous System of Constructing Bridges of Great Span," upon which plan the Forth Bridge and six of the largest bridges in the world have been built.

ROBERT HOLFORD MACDOWALL BOSANQUET, M.A.,

Fellow of St. John's College, Oxford. Barrister. Long and successful devotion to scientific inquiry, as shown by the following list of papers, and the printed copies sent herewith for the use of the Council:—"On an Experimental Determination of the Relation between the Energy and Apparent Intensity of Sounds of Different Pitch" (*Phil. Mag.*, xliv., 381–387); "On Just Intonation in Music; with a Description of a New Instrument for the Easy Control of all Systems of Tuning other than the Ordinary Equal Temperament" (Roy. Soc. Proc., xxi., 131–132); "Note on the Measure of Intensity on the Theories of Light and Sound" (*Phil. Mag.*, xlv., 215–218); "The Theory of the Division of the Octave, and the Practical Treatment of the Musical Systems thus obtained" (Roy. Soc. Proc., xxiii., 390–408); On the Polarization of the Light of the Sky" (*Phil. Mag.*, l., 497–520); "On a New Form of Polariscope and its Application to the Observation of the Sky" (*Phil. Mag.*, ii., 20–28); "On the Hindoo Division of the Octave, with some Additions to the Theory of Systems of the Higher Orders" (Roy. Soc. Proc., xxv., 540–541, xxvi., 372–384); "On the Relation between the Notes of Open and Stopped Pipes" (*Phil. Mag.*, vi., 63–66); "On the Present State of Experimental Acoustics" (*ibid.*, viii., 290–305); "Notes on Practical Electricity" (*ibid.*, xiv., 241–258); "On a Uniform Rotation Machine, and on the Theory of Electromagnetic Tuning Forks" (Roy. Soc. Proc., xxxiv., 445–447); "On Magneto-motive Force" (*Phil. Mag.*, xv., 205–217); "On Permanent Magnetism" (*ibid.*, 257–259, 309–316); "On Self-regulating Dynamo-electric Machines" (*ibid.*, 275–296); "On a Standard Tension Galvanometer" (*ibid.*, xvii., 27–30); "On a Determination of the Horizontal Component of the Earth's Magnetism at Oxford" (*ibid.*, 438–447); "On Electro-Magnets," No. I. (*ibid.*, 531–536); No. II., "On the Magnetic Permeability of Iron and Steel, with a new Theory of Magnetism" (*ibid.*, xix., 73–94); No. III., "Iron and Steel: a New Theory of Magnetism" (*ibid.*, 333–340); No. IV., "Cast Iron, Charcoal Iron, and Malleable Cast Iron" (*ibid.*, xx., 318–323); "Permanent Magnets," No. I. (*ibid.*, xviii., 142–153), No. II., "On Magnetic Decay" (*ibid.*, xix., 57–59); "On the Supposed Repulsion between Magnetic Lines of Force" (*ibid.*, 494–495). With a further list of twenty-seven papers.

SAMUEL HAWKESLEY BURBURY, M.A.,

Barrister-at-Law. Formerly Fellow of St. John's College, Cambridge. Second Classic, and Chancellor's Medallist, and fifteenth Wrangler in the year 1854. Has done much work in Mathematical Physics, espeially in the theories of Electricity and Magnetism and the Kinetic Theory of Gases. Joint author of Watson and Burbury's "Generalized Co-ordinates"; also of Watson and Burbury's "Electricity: Part I. Electrostatics." Author of sundry papers on physical science; for example, the following: Paper in *Phil. Mag.*, January 1876, "On the Second

Law of Thermodynamics in Connection with the Kinetic Theory of Gases"; *ibid.*, 1877, "On Action at a Distance in Dielectrics"; *ibid.*, 1881 (joint author), "On the Law of Force between Electric Currents"; *ibid.*, 1882, "A Theorem on the Dissipation of Energy"; *ibid.*, 1886, "Remarks on Prof. Tait's Paper 'On the Kinetic Theory of Gases'"; "Encycl. Brit." (joint author) Article, "Molecule." Attached to Science, and anxious to promote its progress.

Walter Gardiner, M.A. (Cantab.),

F.L.S., Fellow of Clare College, Cambridge. University Lecturer in Botany. Rolleston Prize, 1888. Author of numerous papers containing original observations and discoveries in Vegetable Physiology, of which the following are the more important:—"The Development of the Water-glands in the Leaf of *Saxifraga crustata*" (*Quart. Journ. Micros. Sci.*, 1881); "On the Continuity of Protoplasm through the Walls of Vegetable Cells" (Phil. Trans., 1883, and Sachs, *Arbeit. d. Bot. Inst. in Würzburg*, Bd. iii.); "On the General Occurrence of Tannin in the Vegetable Cell, and a possible View of its Physiological Significance" (Camb. Phil. Soc. Proc., 1883); "On the Changes in the Gland-cells of *Dionæa muscipula* during Secretion" (Roy. Soc. Proc., 1883); "On the Phenomena accompanying Stimulation in the Gland-cells of *Dionæa dichotoma* (*ibid.*, 1886); "On the Power of Contractibility exhibited by the Protoplasm of certain Plant-cells" (*ibid.*, 1887); "On the Structure of the Mucilage Secreting Cells of *Blechnum occidentale* and *Osmunda regalis*" (*Ann. of Bot.*, 1887).

John Kerr, LL.D.,

Mathematical Lecturer in the Free Church Training College, Glasgow. Discoverer of the optical effects of Electrostatic Stress in transparent solids and liquids; and of the optical effects of magnetism on light reflected from iron.

Arthur Sheridan Lea, D.Sc. (Cantab.),

Fellow, Lecturer in Physiology, and Assistant Tutor of Gonville and Caius College, Assistant Lecturer of Trinity College. University Lecturer in Physiology. Author of the following papers:—"Ueber die Absonderung des Pancreas" (Heidelberg, 1876); "Some Notes on the Urea Ferment" (*Journ. of Physiol.*, vol. iv., 1883); "On a Rennet Ferment contained in the Seeds of *Withania coagulans*" (Proc. Roy. Soc., 1883); "On the Comparison of the Concentration of Solutions of Different Strengths of the same Absorbing Substance" (*Journ. of Physiol.*, vol. v., 1884); "Some Notes on the Isolation of a Soluble Urea Ferment from the Torula Ureæ;" "On the Digestion of Carbohydrates" (Physiol. Soc., May, 1886, *Journ. of Physiol.*, vol. vi., 1885). Author of the Appendix to Foster's "Physiology." Is distinguished for his acquaintance with Physiology. Is attached to Science, and anxious to promote its progress.

Percy Alexander MacMahon, Major, R.A.,

As author of numerous papers in the *Quart. Journ. Math.*, vols. xix.–xxi., Proc. Lond. Math. Soc., vols. xv.–xix., *Amer. Journ. Math.*, vols. vi.–xi., on various subjects in Pure Mathematics, connected with Invariants, Semivariants, Perpetuants, Reciprocants, Partitions, Distributions, and Symmetric Functions. Associate Member of the Ordnance Committee. Instructor in Mathematics at the Royal Military Academy, Woolwich, 1882–88.

Alfred Merle Norman, M.A. (Oxon.),

Hon. Canon of Durham, D.C.L. (Durh.), F.L.S. Eminently distinguished for his researches in Marine Invertebrate Biology, carried on continuously for thirty-seven years. In 1880, Dr. Norman, by the special invitation of the French Government, took part in the deep-sea exploration in the Bay of Biscay, on board *Le Travailleur*, and for his services received, in 1884, the commemoration medal of the Institute of France. He edited, with additions, vol. iv. of "Monograph of British Spongiadæ," by the late J. S. Bowerbank, for the Ray Society. Author, along with T. R. Stebbing, of Crustacean Isopoda of the *Lightning*, *Porcupine*, and *Valorous* expeditions in the Zool. Soc. Trans., 1886; along with G. S. Brady, F.R.S., "Monograph of the Marine and Fresh-Water Ostracoda of the North Atlantic and North-West Europe," Roy. Dubl. Soc. Trans., 1889; "Report on the Crustacea of the Faroe Channel—H.M.S. *Knight Errant*" (1880). Author of over forty other reports published in the Brit. Assoc. Reports, *Ann. and Mag. Nat. Hist.*, *Journ. Conchol.*, *Journ Micros. Sci.*, &c., &c. Chairman of the Jury on Natural History at the Fisheries Exhibition, 1883. Possessor of Collections of the Invertebrate Fauna of the North Atlantic and Arctic Oceans, which are probably unequalled, and are always at the disposal of authors, as may be seen in every work published in Britain on the subject for the last twenty years.

William Henry Perkin, Jun., Ph.D.,

F.I.C., F.C.S. Professor of Chemistry in the Heriot Watt College, Edinburgh. Formerly Privatdocent and Assistant in the Chemical Research Laboratory of the University of Munich. Distinguished as an Investigator, especially in devising new synthetic methods for the preparation of organic compounds containing closed carbon chains and in studying the properties of this important class of substances. This work has attracted great attention, both in this country and on the Continent. Author, and joint author, of upwards of fifty papers, published partly in the Journal of the Chemical Society, and partly in the *Berichte* of the German Chemical Society. Amongst others—"Condensation Products of Oenanthol," "Condensation Products of Isobutylaldehyde," "Benzoylacetic Acid and some of its Derivatives," "Synthetical Formation of Closed Carbon Chains," "Action of Trimethylene Bromide on Ethylic Acetoacetate, Benzoyl-acetate and Malonate," "Action of Ethylene Bromide on Ethylic Aceto-acetate and Benzoyl-acetate," "Action of Ethylene Bromide on Ethylic Malonate," "Trimethylene Derivatives," "Some Derivatives of Tetramethylene," "Pentamethylene Dicarboxylic Acid," "Some Derivatives of Hexamethylene," "Derivatives of Hydrindonaphthene," "New Synthesis of Naphthalene Derivatives," "Dehydracetic Acid," "Phenylenediacrylic Acid," "Paranitro-benzoylacetic Acid," "Ethylic Diacetyladipate," "On Kamala," and "On Berberine." As a teacher he has been especially successful in suggesting and directing research work, as evinced by the number of papers he has published in conjunction with his students.

Spencer Umfreville Pickering, M.A.,

F.C.S. Professor of Chemistry at Bedford College. Distinguished as as investigator of the thermal changes attending dissolution of salts. Author of papers on "The Action of Sulphuric Acid on Copper," "The Action of Hydrochloric Acid on Manganese Dioxide," "Sodium Thiosulphate and Iodine," "Basic Sulphates of Iron," "Sulphides of Copper," "The Constitution of Molecular Compounds," "Modifications of Sodium Sulphate," "Heat of Dissolution of Potassium and Lithium Sulphates," "Calorimetry of Magnesium Sulphates," "Modifications of Double Sulphates," "Multiple Sulphates," "Influence of Temperature on the Heat of Chemical Combination," "Water of Crystallization," "Heat of Hydration of Salts," and others, in all about forty, published in the Journ. Chem. Soc., the *Phil. Mag.*, and the *Chem. News*.

Isaac Roberts, F.R.A.S.,

F.G.S., V.-P. of the Literary and Phil. Soc. of Liverpool. Discovery and publication, by aid of photographic methods, of Nebulæ in Andromeda, Orion, the Pleiades, and Vulpecula. Charting by photography a considerable portion of the stars of the northern hemisphere. Rediscovery of a minor planet by photography. Improvements in the apparatus and methods for giving long exposures in stellar photography. Invention of a machine for accurately charting the stars in a permanent manner by engraving them upon metal plates directly from the photographic negatives. The machine is also adapted for measuring the positions and magnitudes of the stars (*Monthly Notices*, Roy. Astron. Soc.). Determination of the Vertical and Lateral Pressures of Granular Substances (Proc. Roy. Soc., 1884); Investigation of the Movements of Underground Waters in Porous Rocks. Various papers on astronomical and geological subjects (see "Cat. of Sci. Papers, Roy. Soc."). Often finding opportunities of rendering valuable aid to those engaged in scientific research.

DAVID SHARP, M.B., C.M. (Edin.),

President of the Entomological Society of London. Hon. Memb. Inst. New Zealand, &c. Distinguished as an Entomologist, especially for his knowledge of the order Coleoptera, many of the more intricate groups of which he has studied with reference to their structure, classification, geographical distribution, &c.; is attached to Science, and anxious to promote its progress. Author of the following memoirs:—"On Aquatic Carnivorous Coleoptera or Dytiscidæ," forming Vol. II. (Ser. 2) of the Scient. Trans. Roy. Dubl. Soc., 1879-82; "Memoirs on the Coleoptera of New Zealand" (*ibid.*, 1886); and, with the Rev. T. Blackburn, "Memoirs on the Coleoptera of the Hawaiian Islands" (*ibid.*, 1885); besides upwards of one hundred minor contributions to the Transactions of various Societies in England and on the Continent. Has also just completed a memoir on the Dytiscidæ, Staphilinidæ, &c., of Mexico and Central America, being Coleoptera, Vol. I., Part 2, of Messrs. Godman and Salvin's "Biologia Centrali-Americana" (pp. 824, pls. 19), and is now engaged in studying the Clavicornia and Rhynchophora for the same work. Since 1885 he has written the whole of the Insecta (except the Neuroptera) for the *Zoological Record*.

J. J. HARRIS TEALL, M.A.,

F.G.S. Has taken a leading place among the petrographical geologists of this country, having enriched the literature of the science with important original contributions. Among these, special mention may be made of the following:—"The Patton and Wicken Phosphatic Deposit" (Sedgwick Prize Essay, 1875); "Petrological Notes on some North of England Dykes" (*Quart. Journ. Geol. Soc.*, 1884, p. 209); "On the Chemical and Microscopical Characters of the Whin Sill" (*op. cit.*, p. 640); "The Metamorphism of Dolerite into Hornblende-schist" (*op. cit.*, 1885, p. 133); "The Lizard Gabbros" (*Geol. Mag.*, 1 p. 481); "On the Origin of certain Banded Gneisses" (*op. cit.*, 1887, p. 484). In 1888 he published a valuable treatise on "British Petrography," containing the results of much original research, and presenting for the first time a general review of the microscopic characters of all known British rocks. In the same year he was appointed to the Geological Survey, where he is specially charged with the investigation of the petrography of the crystalline schists.

RICHARD THORNE THORNE, M.B. (Lond.),

F.R.C.P. Assistant Medical Officer to H.M. Local Government Board. Has made numerous original observations in regard to the spread of disease, and especially on an epidemic of typhoid fever, and its dissemination by water at Caterham and Redhill. Author of "The Use and Influence of Hospitals for Infectious Diseases" (Proc. of the Internat. Sanit. Conference at Rome); and of a large number of Reports on Public Health to the Privy Council and Local Government Board. He was appointed along with Sir W. G. Hunter to represent Great Britain at the International Sanitary Conference of Rome, 1885. Is distinguished for his acquaintance with Sanitary Science, as shown by his being President of the Epidemiological Society, Lecturer on Public Health at St. Bartholomew's Hospital, Examiner in Public Health to the University of Oxford, the University of London, and the English Conjoined Board.

WALTER FRANK RAPHAEL WELDON, M.A.,

Fellow of St. John's College, Cambridge. University Lecturer on the Advanced Morphology of Invertebrates in the University of Cambridge. Author of: (in the *Quart. Journ. Micros. Sci.*, 1883-88) "Note on the Early Development of *Lacerta muralis*"; "On the Head-kidney of *Bdellostoma*"; "On the Supra-renal Bodies of Vertebrata"; "*Dinophilus gigas*"; "*Haplodiscus piger*"; (in the Proc. Zool. Soc., 1884) "On some Points in the Anatomy of *Phœnicopterus* and its Allies"; "Note on the Placentation of *Tetraceros quadricornis*"; "Notes on *Callithrix gigot*"; (in the Proc. Roy. Soc.) "Note on the Development of the Supra-renal Bodies of Vertebrates"; "Preliminary Note on a Balanoglossus Larva from the Bahamas"; Note on the last paper; and a Report of Investigations into the Crustacean Fauna of Plymouth Sound, carried on in the laboratory of the Marine Biol. Assoc., in accordance with instructions from a Committee appointed by the Royal Society.

NOTES.

M. EUGÈNE PELIGOT, the eminent French chemist, died at Paris on April 15. He was born on March 24, 1811. In 1832 he was admitted to the laboratory of J. B. Dumas, and three years afterwards he became Professor of Chemistry at the École Centrale. In 1846 he succeeded Clément Desormes at the Conservatoire des Arts et Métiers; and here, until recently, he continued to deliver courses of lectures on general chemistry. He also lectured at the National Agricultural Institute on analytical chemistry applied to agriculture. For more than 40 years he was connected with the French Mint, and at the Hôtel des Monnaies he lived and died. M. Peligot was elected a member of the Paris Academy of Sciences in 1852, and in 1885 he received the dignity of a Grand Officer of the Legion of Honour.

THE death of Dr. F. Soltwedel, Director of the Botanical Station at Semarang, in Java, is announced. He was a very energetic botanist, especially in the direction of applied botany.

WE learn from the *Botanisches Centralblatt* that Mr. Thomas Hanbury, of Mortola, near Mentone, has offered to defray the expense of the erection of a building in the Botanic Garden at Genoa, to provide a laboratory, lecture-rooms, and space for botanical collections. The building is to become the property of the University of Genoa, and will be erected under the direction of Prof. Penzig, the Director of the Botanic Garden; and it is hoped that it will be completed by the time of the International Botanical and Geographical Congress to be held in Genoa at the time of the great Columbus Festival in 1892. It is intended that the new Institute shall bear the name of the "Hanbury Botanical Institute."

DURING his visit to the Canaries, in 1889, made for the purpose of taking observations on the atmospheric absorption of the solar spectrum, Prof. O. Simony, of Vienna, landed upon the lonely rock of Zalmo, near the Island of Ferro, and discovered a very curious lizard, which was subsequently described by Prof. Steindachner (*Anz. k. Ak. Wiss. Wien*, 1889, p. 260) as *Lacerta simonyi*. At the request of Lord Lilford, Canon Tristram has also recently visited the same spot, and obtained some examples of this lizard, which Lord Lilford has presented to the Zoological Society's collection. Simony's Lizard is a fine large species, very dark in colour, but obviously allied to the well-known *Lacerta ocellata* of Southern Europe.

THE fifth of the series of photographic exhibitions at the Camera Club, will be open for private and press view on Monday, May 5, at 8 p.m., and on and after Tuesday, May 6, it will be open to visitors on presentation of card. It will consist of photographs by the late Mrs. Julia Cameron.

THE French Exhibition, which is about to be opened at Earl's Court, will illustrate the arts, inventions, products, and resources of France and her colonies, and will, it is said, include many of the best objects shown at the Paris Exhibition of last year.

AN archæological museum has been established in connection with the University of Pennsylvania. *Science* says it contains—in addition to the American specimens—a fine collection of flints, bronze implements, and pottery from Europe, as well as objects from Asia, Africa, and the South Sea Islands. At the same University a museum of economic botany is about to be formed. It will consist of all kinds of woods, vegetable fibres, grains and drugs, arranged so as to illustrate the processes of manufacture from the raw product, and the various uses to which each material may be put.

The Marine Biological Laboratory at Wood's Holl, Massachusetts, will hold its third session during the approaching summer. The Institution has been so successful that a library, a lecture-room, and six private laboratories have lately been added to it.

The following are the arrangements for the science lectures to be given at the Royal Victoria Hall during May:—May 6, birth and death of mountains, W. W. Watts; May 13, London water supply, Prof. Bonney; May 20, how a photograph is taken, Dr. J. A. Fleming.

Dr. H. Ross has been appointed Lecturer on Botany at the University of Palermo, and Dr. G. B. De Toni Lecturer on Botany at the University of Padua.

Morot's *Journal de Botanique* for March 1 contains an interesting biographical sketch of the late M. E. Cosson, together with a bibliography of his numerous contributions to botanical literature.

At the last meeting of the Scientific Committee of the Royal Horticultural Society, the Rev. C. Wolley Dod gave an account of several diseases of plants in his garden, and commented on the difficulty of finding curative means, or of hearing of other suggestions than burning. He first alluded to a species of smut (Ustilago) on *Primula farinosa*, which appeared to be indigenous, as the plants were collected in Lancashire; and although it was grown with *P. denticulata*, the smut was confined to the former species. *Æcidium ficariæ* had attacked his hellebores. In this case, a drier soil was suggested as likely to prove effective in ridding the plants of the fungus. The "Lily spot," due to *Polyactis cana*, usually appearing late in summer, had been seen in April upon tulips, and apparently the same species on daffodils. It was suggested that a mixture of sulphate of copper and quicklime would prove effective, as in the case of vines. *Puccinia Schrateri* had occurred on daffodils from Portugal, and also upon the common double sorts.

At the meeting of the Society of Arts on April 23, Mr. W. Whitaker read a paper on "Coal in the South-East of England." Afterwards some remarks were offered by Mr. Topley, Prof. Rücker, Prof. McKenny Hughes, Dr. Archibald Geikie, who presided, and the author of the paper. Dr. Geikie said he thought everyone present must share his feeling of surprise and pleasure at finding that a number of geologists could come together and discuss a question like this with so little difference of opinion, and it might be taken as strong evidence that on this particular question there was nothing to fight about. He knew of no recent instance where a true scientific induction had been followed with such brilliant success as the one now brought forward. It had been discussed more or less academically by geologists for some sixty years, bit by bit evidence had accumulated as they went further and further below the surface, and at last it had been definitely proved that coal existed in the south-east of England. An ordinary observer would have found it almost impossible to imagine, when standing on a sunny day in the south of Kent, that coal was to be found there hundreds of miles from the great coal-fields, and it would be difficult to make such a person understand why geologists should pitch upon such a spot as a likely place for a colliery. Mr. Whitaker had gone over the evidence, and everyone must have realized how the conclusion had been arrived at, and how admirably the inference had been proved by experiment. But, as Prof. Hughes had said, they were very far from having reached a complete picture of the geography of the rocks that underlie the Secondary rocks of the south-east of England. They were groping their way by degrees, and in the process coal had been discovered. He did not imagine there could be any large continuous coal-field there; it could only exist in detached basins (even allowing for overthrusts), separated by uprises of older rocks. Further to the west they knew nothing by actual borings, and in no other way could anything like a map of the subterranean geology be obtained. It might be surmised with some probability that, between Bristol and the areas where borings had been made, there might be more extensive coal-fields than were at all likely to be found in the extreme south-east. They had heard of the wonderful plication of the Carboniferous strata in the west of France, but it must be remembered that not only had the Coal Measures undergone these movements, but the secondary rocks which overlay them had also been crushed, folded, and pushed over each other in the manner which any one might see on the south coast of Dorsetshire; and this process must have considerably thickened the Secondary rocks, the consequence of which was that you might bore through the same stratum sometimes a very long way. It was absolutely necessary that, in the prosecution of this matter, the practical man should go hand in hand with the man of science, otherwise a great deal of time, money, and labour would be wasted.

The Norwegian Government has laid before the Storthing a proposal to the effect that two-thirds of the cost of the Norwegian Polar Expedition under the command of Dr. Frithjof Nansen shall be defrayed by the State: the conditions being—that the expenses do not exceed 200,000 kroner (about £10,000); that if the expedition proves successful the vessels and scientific instruments used during the voyage shall become the property of the State; and that the Christiania University shall receive such specimens from the scientific collections as the senate shall select.

The Director of the Observatory at Tusa, in Sicily, noted two short but severe shocks of earthquake at noon on April 15. No damage was caused.

A shock of earthquake was felt at Lisbon on the morning of April 28.

M. E. Leyst, Superintendent of the Observatory of Pawlowsk, near St. Petersburg, has contributed to vol. xiii. of the *Repertorium für Meteorologie* an important investigation upon the influence of the times of reading the maximum and minimum thermometers upon the results deduced from them.

The Administration Report of the Meteorological Department of the Government of India for the year 1888–89 gives an account of some important changes in the working of the service since January 1, 1889. The change of the hour of morning observations from 10 a.m. to 8 a.m. has accelerated the publication of the Daily Weather Reports, and this result is much appreciated in Calcutta and Bombay. A uniform system of rainfall observations throughout India, and the telegraphing of rainfall information to Simla, enable the Department to prepare comprehensive rainfall charts and tabular statements for each week during the monsoon season. A local Daily Weather Report and Chart is now prepared at Bombay, in order to give early information to the commercial community, in a form similar to the Reports published at Calcutta. The Bombay Chamber of Commerce has contributed liberally towards the expenses of this service. The collection of information from ships in the Arabian Sea and Bay of Bengal is to be extended. This is essential for the investigation of the causes of the origin of storms; and, if sufficient material be collected, charts will be prepared for each day for two or three years. The charts must necessarily appear about three months after date. The work of observation with regard to storms is acknwledged to have been hitherto very defective. A small payment will be made in future for this service, and several valuable series of observations during dust-storms, &c., have already been received. The staff in India being insufficient to discuss the mass

of material which has accumulated during the last 13 years, the Government has wisely given a grant for the discussions of the more important series to be carried out by distinguished meteorologists in Europe. Several important investigations by the Indian staff are in a more or less advanced state of preparation, including an account of the cyclonic storms of August 1888, and of September 13–20, 1888; a paper on the relation of sunspots to weather, as shown by meteorological observations in the Bay of Bengal from 1855–78; and an account of the storm in the Arabian Sea in June 1887. At the commencement of the year under report, there were 161 observatories contributing regular observations.

M. P. LAFOURCADE, in a paper on the great bustard (*Revue des Sciences Naturelles Appliquées*), says that this bird is becoming very scarce in France, as it can flourish only in large uncultivated spaces. In Champagne and Provence it is never

SOME observations on the brain-weight of new-born infants are given by Herr Mies in a Vienna medical paper. From 203 weighings he found the brains of male children to weigh on the average 339·3 grammes (say 11·9 oz.), and those of females 330 grms. (say 11·6 oz.). The lightest was 170 grms., and the heaviest 482 grms. The brain-weight of the new born infant is to the body-weight as 1 : 7 to 8·5. Only children living at the time of birth were considered.

AT the meeting of the Royal Society of Queensland on February 17, Mr. W. Saville-Kent presented some interesting notes on the embryology of the Australian rock oyster (*Ostrea glomerata*). He mentioned that in connection with the investigation of this subject he had been carrying on a series of experiments with the view of accurately determining the influence upon the embryonic brood that is exercised by the advent of fresh-water floods or other sudden changes in the salinity of the water. Some important results had been obtained. From a series of oysters recently purchased in the market a fully matured male and female were selected for experiment. Portions of milt and ova from these two individuals were abstracted and commingled under precisely the same conditions, and placed respectively in water of three different degrees of salinity. The first admitted was placed in sea-water of the full ordinary strength. In the second there were equal proportions of salt and fresh water, and in the third one part of salt water to three of fresh. As a result, the ova placed in the equal admixture of salt and fresh water exhibited active vitality, and were quickly speeding in their developmental career. Of the ova placed in pure sea-water, but few were fructified, and these developed very slowly. Those, finally, placed in the water containing only a one-fourth proportion of sea-water were entirely deprived of life, and soon began to disintegrate. To this last circumstance Mr. Saville-Kent called special attention. It indicated, he said, the pernicious effect upon breeding oysters that might be exercised by heavy floods, and opened out a wide field for further inquiry.

A PAPER on the fossil butterflies of Florissant, Colorado, by Mr. Samuel H. Scudder, is included in the eighth Annual Report of the Director of the United States Geological Survey, and has now been reprinted separately. The specimens were found "in presumably Oligocene beds." There are altogether seven species, and they all belong to extinct genera. Their general aspect is "distinctly sub-tropical and American, while the Tertiary butterfly fauna of Europe is derived in the first place rom the East Indies, in the second from sub-tropical America, and in the third from home." With regard to one interesting point Mr. Scudder writes as follows:—"In living butterflies, as we ascend the scale of families we find an increasing atrophy of the front legs. In the two lower families, *Hesperidæ* and *Papilionidæ*, they are similar in structure to the other pairs, being normally developed. In the *Lycænidæ* (including in this the sub-families *Lemoniinæ* and *Lycæninæ*) they are atrophied in the male to a greater or less extent, with the loss of the terminal armature, while still perfect in the female. In the highest family, *Nymphalidæ*, with the single exception of the little group *Libytheinæ*, which agrees with the *Lycænidæ*, they are aborted in both sexes, often to an excessive extent. Now, in *Prolibythea* we have the forelegs of the female preserved, and in *Nymphalites* the foreleg of the male; in both cases they agree in all essential points with what we should expect to find in living forms belonging to the same groups, showing that at the earliest epoch at which butterflies are yet known these peculiar differences, marking the upward progression of forms, were already in existence. We must therefore look for the proofs either of great acceleration in development when butterflies first appeared, or of the existence of butterflies at a far earlier period than we yet

IN the yearly report of the East Siberian branch of the Russian Geographical Society, it is shown that the Miocene deposits in the middle parts of the provinces of Tomsk and Yeniseisk are much greater in extent and thickness than has hitherto been supposed. They contain, besides thin layers of coal, a rich flora, samples of which have been secured by M. Klementz. Leaves and needles of *Acer*, *Betula*, *Pinus Lopatini*, *Segusia*, *Sternbergi*, *Glyphostrobus*, *Magnolia*, *Ulmus*, *Populus*, and so on, are found in great quantities, and it seems probable that the Miocene flora of Siberia will prove as abundant and as suggestive of changes of climate as that of Switzerland.

AN interesting and successful experiment in technical education is described in a resolution of the Indian Education Department, granting an increase of over 16,000 rupees in expenditure on schools in Sind. Appended to the resolution is an extract from a letter of Mr. Jacob, Inspector of Schools, in which he gives some details of the practical system of technical education which has been instituted in the Naushahro schools by Khan Bahadur Kadirdad Khan. The industries taught embrace Sind embroidery, tailoring, joining, and cabinet work, smith's work in iron and brass, electro-plating, mason's work, pottery, &c., and the attendance at all the classes is continually increasing. The boys in the workshops are divided into "gangs," each headed by a senior boy who has displayed exceptional skill. The schools are in close touch with the market; and, as orders come in, they are distributed among the gangs, and the profits of the work are divided among the members of the gang in proportions fixed by the teacher, and regulated by the degree of skill possessed by each individual. The industrial school for girls is most popular, and suggests new possibilities in the extension of female education; for it is found that the opportunity of earning money keeps the girls at school up to a later age than has hitherto been usual. Mr. Jacob says that the schools have created an extraordinary interest among the industrial classes, both Mahomedan and Hindu.

IN a paper on the aborigines of Australia, printed in the current number of the Journal and Proceedings of the Royal Society of New South Wales, Mr. W. T. Wyndham speaks of the skill with which the natives use stone implements. "They turn out work," he says, "that you would hardly believe possible with such rough implements. They show great ingenuity, particularly in making their harpoon heads for spearing dugong and fish; instead of shaving the wood up and down with the grain as a European workman would do, they turn the piece of wood for a spear-head round and round, and chip it off across the grain, working it as wooden boxes are turned on a lathe. I have often sat and watched them doing this."

According to an official estimate, there are 170,000 wolves in Russia; and the loss caused by the destruction of sheep and swine by wolves is so great that it cannot be even approximately estimated. The reward paid for each wolf killed is 10 roubles. The number killed in 1889 in the single government of Wologda was 49,000, and in the government of Kasan 31,000. The number of human beings killed by wolves during the year was 203.

Mr. John Murray has issued an abridged and popular edition of Mr. Paul du Chaillu's "Adventures in the Great Forest of Equatorial Africa and the Country of the Dwarfs." While recognizing the work that has been done by later travellers in the regions with which his name is associated, Mr. du Chaillu says, in his new preface, that, so far as he is aware, no white man has been able since his time "to penetrate to the haunts of the gorilla and bring home specimens killed by himself."

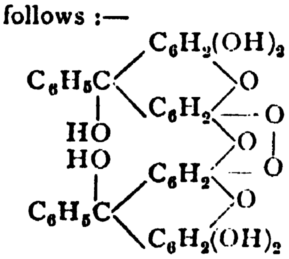
Part 19 of Cassell's "New Popular Educator" has been issued.

We have received "The Medical Register" and "The Dentists' Register" for 1890. Both works are printed and published under the direction of the General Council of Medical Education and Registration of the United Kingdom.

The seventh annual issue of the "Year-book of the Scientific and Learned Societies of Great Britain and Ireland" (C. Griffin and Co.) has been published. It comprises lists of the papers read during 1889 before Societies engaged in fourteen departments of research, with the names of their authors. The work has been compiled from official sources.

The following note on the words "cold-short" and "red-short" appears in *Engineering* of the 25th ult. Some of our readers may perhaps be able to throw light on the subject:—The words "cold-short" and "red-short" are so expressive that their etymology would seem at first sight to be entirely free from difficulty, but such is not the case. The earliest form of "cold-short" occurs in Philemon Holland's translation of Pliny's "Natural History" (1601) where it appears as "colsar." Vernatt and Whitmore, in their patent for the manufacture of iron granted in 1637, speak of "colshire" and "coleshire" iron, whilst Dud Dudley, in his famous tract "Metallum Martis" (1665), calls it "coldshare" iron. A still further variation appears in the Philosophical Transactions for 1693, in the course of a curious paper, written in 1674, giving an account of the hematite ores of Lancashire, where the writer speaks of "coldshire" and "redshire" iron. Andrew Yarranton, in his "England's Improvement by Land and Sea" (1677), uses the word "coldshore," and in Moxon's "Mechanick Exercises," published in the same year, red-short iron is described as "red-sear." The earliest known instance of "cold-short" and "red-short" is in a rare folio tract of 4 pages bearing the title "Beware of Bubbles," which, though undated, must, from internal evidence, have been issued in 1730. It forms one of a number of broadsides circulating about the time referring to a patent for the manufacture of iron taken out by Francis Wood, the well-known manufacturer of "Wood's halfpence," so unmercifully satirized by Swift in the "Drapier Letters." The words "cold-short" and "red-short" are at the present moment occupying the attention of the editor of the "New English Dictionary on Historical Principles," now in course of publication by the Clarendon Press, and if any of our readers are able to throw light upon the etymology of "cold-short" and "red-short" their suggestions will be gladly welcomed by the editor, Dr. Murray, Banbury Road, Oxford.

A new colouring matter from pyrogallol, $C_6H_3(OH)_3$, and benzotrichloride, $C_6H_5 . CCl_3$, is described in the current number of *Liebig's Annalen*, by Drs. Doebner and Foerster, of the University of Halle. When pyrogallol and benzotrichloride are heated to 160° C. in the proportion of two molecules of the former to one of the latter until no more hydrochloric acid is evolved, a fused mass is obtained which dissolves in alkalies with the production of a fine blue colour. The powdered product of the fusion is of a dark brown colour with a greenish metallic lustre. It may be obtained pure from solution in hot glacial acetic acid in the form of dark green crystals, which under the microscope appear as bright red transparent plates by transmitted light. The substance is almost insoluble in water, benzene, or carbon bisulphide, but is more soluble in alcohol and ether, and in hot chloroform. It dissolves in a hot solution of sodium acetate with production of a deep red colour. Caustic alkalies readily dissolve the pure crystals with production of the same blue colour as that yielded by the crude product of fusion. When the solution is just neutralized the colour is a bluish-violet, but the least excess of alkali reproduces the magnificent blue colour. Strong sulphuric acid dissolves the crystals with formation of a soluble sulphonic acid of a fine violet tint. Most metallic salt solutions yield with neutral solutions of the ammonium salt precipitates of the nature of "lakes" of varying composition and of various shades of bluish-violet. The colours produced by salts of aluminium and iron are perhaps the most striking. The yield of the new substance is very good, and generally amounts to about sixty grams of pure crystals for every hundred grams of pyrogallol employed. As regards its composition and constitution, its empirical formula is found to be $C_{38}H_{24}O_{11}$. It evidently contains four phenol hydroxyl groups, for it reacts with acid chlorides and anhydrides with production of compounds containing four acid radicals. The acetyl compound, $C_{38}H_{20}O_{11}(C_2H_3O)_4$, forms bright red crystals, melting at 208° C., which are decomposed by soda with formation once more of a blue colour. The benzoyl compound, $C_{38}H_{20}O_{11}(C_7H_5O)_4$, consists of thin red prisms possessing a brilliant green lustre, and melting to a deep red liquid at 251°. The substance also yields a hydro-reduction product with zinc dust and glacial acetic acid of the composition $C_{19}H_{14}O_5$; this reduction-product forms beautiful long colourless needles of silky lustre, which rapidly reoxidize in air, and especially on heating, to the original compound. Even if the needles are allowed to remain a short time in their mother-liquor they gradually become tipped with red, exhibiting an exceptionally pretty effect. The constitution of this hydro-body is shown to be $C_6H_5CH\left\langle\begin{matrix} C_6H_2(OH)_2 \\ C_6H_2(OH)_2 \end{matrix}\right\rangle O$, from which, taking into account the fact that four phenol hydroxyl groups are shown to be present by the mode of reaction with acid chlorides and anhydrides, the constitution of the new colouring matter is concluded to be as follows:—



The name which the discoverers propose for the compound is pyrogallol-benzeïn.

The additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus* ♀) from India, presented by Mrs. Pendry; a Brown Bear (*Ursus arctos* ♂) from Russia, presented by Miss Evelyn Muir; a Bateleur Eagle (*Helotarsus ecaudatus*) from East Africa, presented by Dr. E. J. Baxter; an Elliot's Pheasant (*Phasianus ellioti* ♀) from China, a Cape Weaver Bird (*Hyphantornis capensis* ♂) from South Africa, a Red-eyed Ground Dove (*Pipilo erythrophthalmus*) from North America, presented by Mr. Wilfred G. Marshall; a

Tuatera Lizard (*Sphenodon punctatus*) from New Zealand, presented by Mr. J. Catheson Smith; an Egyptian Ichneumon (*Herpestes ichneumon*) from North Africa, two Grey Ichneumons (*Herpestes griseus* ♂ ♂), two Alexandrine Parrakeets (*Palæornis alexandri*) from India, two White Pelicans (*Pelecanus onocrotalus*), South European, deposited; a Musk Deer (*Moschus moschiferus* ♂) from Central Asia, seven Bearded Lizards (*Amphibolurus barbatus*), three —— Lizards (*Amphibolurus muricatus*), a Gould's Monitor (*Varanus gouldi*) from Australia, purchased; a Barnard's Parrakeet (*Platycercus barnardi*) from South Australia, received in exchange; an Indian Muntjac (*Cervulus muntjac*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

OBJECTS FOR THE SPECTROSCOPE.

Sidereal Time at Greenwich at 10 p.m. on May 1 12h. 39m. 6s.

Remarks.

(1) During his spectroscopic survey of nebulæ in 1868, Lieut. Herschel noted that this gave a bright line spectrum. The three principal nebular lines and G were observed, but, as I have before remarked, other lines may possibly be found if carefully looked for. Some of the lines observed in other nebulæ, namely D_3 and lines near λ 559, 521, 517, 470, and 447, may be expected. In the General Catalogue the nebula is described as "Very bright; large, round; very suddenly much brighter in the middle to a nucleus; barely resolvable."

(2) According to Secchi, Vogel, and Dunér, this star has a magnificent spectrum of Group II., all of the ten ordinary bands being well visible. The band near D and the one less refrangible (Dunér's 2 and 3) are very wide, but the others are relatively narrow, though strongly marked. Dunér notices the peculiarity that band 5 (λ 546) is double. This should be further examined; the apparent duplicity may be simply due to the superposition of a strong line upon the dark fluting of lead. As the star is an exceptionally bright one for this group, comparisons with the bright flutings of carbon should be made, with the object of further confirming the cometary character of this group of stars.

(3) This is a star which has hitherto been classed with stars like the sun. The usual more detailed observations are required to determine whether the temperature of the star is increasing or decreasing.

(4) A star of Group IV. (Vogel). If the colour given by Vogel is correct, one would expect the metallic lines to be fairly well developed in this star, and it would probably be no longer classed in Group IV. The stars of this group are usually white or bluish-white, the yellowish-white stars generally falling in the later stages of Group III. or the earlier stages of Group V.

(5) The colour and spectrum of this variable have not yet been recorded, as far as I can determine, and the approaching maximum of May 5 may therefore afford a good opportunity of observing it. The range of variability is from 8·0 to 14·0 in a period of about 219 days.

(6) As this comet is travelling northwards and is gradually increasing in brightness, it may be well to note a few of the chief points to which attention should be directed in spectroscopic observations. The positions given are for Berlin midnight, and are reprinted from NATURE, vol. xli. p. 571.

Observations of the spectrum of a comet at one time only are now of little value, as there can be no doubt that the spectrum is subject to changes with the variations of temperature due to varying distances from the sun. The question now is: What is the precise nature of these changes? From a discussion of all the observations made up to 1888, Prof. Lockyer has laid down what he considers to be the most probable sequence; but as yet there has been no opportunity of testing his views by continued observations of one comet. According to his view, the spectrum of a comet near aphelion is like that of a planetary nebula, consisting simply of a bright line near λ 500. This, it will be remembered, was observed by Dr. Huggins in the comets of 1866–67. As the temperature increases, the spectrum of carbon begins to appear; at first the low-temperature spectrum (perhaps better known as the spectrum of carbonic oxide) makes its appearance, and afterwards the spectrum of hot carbon (commonly known as the hydrocarbon spectrum). The principal flutings in the first spectrum are near λ 483, 519, and 561, and those in the second are compound flutings with their brightest maxima near λ 564, 517, and 473. As the temperature goes on increasing, bright flutings of the metals manganese and lead (λ 558 and 546) are added to those of carbon, the chief effect of their presence being a variation in the appearance of the band near λ 564. With a still further increase in temperature, fluting absorptions of manganese and lead replace the corresponding radiations, and apparently shift the position of the citron band from λ 564 to 558 or 546, according to the preponderance of one element or the other. At the highest temperatures, which are only attained by comets which approach very close to the sun, bright lines of sodium, iron, manganese, and other substances, appear, as in Comet Wells and the Great Comet of 1882. (For further details, see Roy. Soc. Proc., vol. xlv. p. 189.)

For comparison spectra, a spirit lamp, and small quantities of magnesium and the chlorides of manganese and lead are all that are likely to be required, unless complete measurements of wavelengths are attempted. The chief fluting in the spectrum of magnesium will serve for comparison with the line 500.

Variations in the form of a comet have not yet been associated with spectroscopic changes. A. FOWLER.

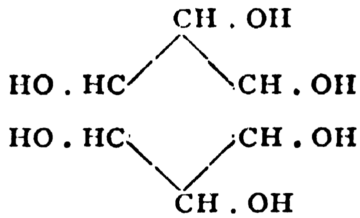
COMETS AND METEOR STREAMS.—In the cases of the Leonides and Andromedes, the annexed comet appears to be at the head of the swarms, and Schiaparelli and others have inferred from this fact that a comet is broken up by tidal disturbances. Other influences besides tidal action may cause it however, and M. Bredichin, in his memoir "Sur les étoiles filantes," showed how meteorites became detached from the central condensation by explosions, and describe orbits that differ according to the value of the initial velocity towards the sun, and the angle made by its direction with the radius vector. In a later communication (*Bull. Soc. Impér. des Naturalistes de Moscou*, 1889, No. 4) the form of the orbits generated by explosions in the comet, and their relation to such meteoritic streams as the Leonides and Andromedes, has been investigated. It is noted that in general the less the eccentricity of the generated ellipse, the more clearly marked are periods of maxima in falls of meteors. With the increase of eccentricity the maxima become less marked, and in the case of a parabolic orbit feeble falls occur each year. The regular periodicity of maxima would favour the formation of a meteoritic stream by a single eruption; in some cases, however, a series of eruptions must have taken place. M. Bredichin thinks that in the Leonid stream a single eruption was excessively preponderant, in the Andromedes a series of eruptions would appear to have occurred. Other cases have also been studied in detail. A meteorite is regarded as a portion of a large comet ejected from the parent mass by an eruption, and an investigation of the number of appearances of bright meteors indicates the connection between them and shooting stars, and, as would be expected, both have maxima when the earth is passing through a meteoritic stream. Although the connection between comets and meteorites is not a matter of doubt, the above investigation demonstrates it from a new point of view. It seems most probable, however, that the disintegration of a meteoritic swarm that has entered our system is caused by tidal disturbances as well as the repulsive action which is the cause of a comet's tail.

STELLAR PROPER MOTIONS.—The number of known stars having proper motions is relatively considerable, but they are much dispersed through astronomical records; M. J. Bossert, however, in the *Bulletin Astronomique* for March 1890 gives an excellent synoptical table of such stars. Many calculations are facilitated by such a table, showing the elements that may vary the position of a star; and in a research on the motion of the solar system it is invaluable. All stars are included whose annual motion is 0″·5 or more. The list has been culled from every known catalogue and astronomical record, but the results

have not been accepted without an examination. Thus it is pointed out that the large proper motion given by Arago in his "Popular Astronomy" for the star in Argus, No. 2151 B.A.C., should be rejected, the comparison of Lacaille's observations with those of Stone and Gould giving, in fact, a motion of about 0″·2 for this star. The magnitude, co-ordinates for 1890·0, proper motion in right ascension and declination, the resultant motion, the direction of this motion, and the authority are given for each star.

OPTICAL ISOMERIDES OF INOSITOL.

DURING the last few months, whilst the brilliant researches of Prof. Emil Fischer on the synthetical production of the glucoses have been attracting so much attention, some very interesting work has been done on a compound which was formerly supposed to belong to the glucose group, viz. inosite. Maquenne, in 1887, showed that this compound, which is fairly widely distributed throughout the animal and vegetable kingdoms, is not a sugar, but a hexahydroxy-derivative of hexamethylene, having the constitutional formula—



It is an alcohol, and in accordance with the usual English nomenclature the name inosite must therefore be altered to inositol.

M. Maquenne has recently examined a compound obtained from the manna-like exudation of one of the Californian pines (*Pinus lambertiana*), and termed β-pinitol. He found that its formula is $C_7H_{14}O_6$, and that on heating with hydriodic acid it is resolved into methyl iodide and a substance which has the same composition as inositol, and resembles it in most of its properties, but melts at a higher temperature and rotates the plane of polarization to the right ($[\alpha]_D = 65$), inositol being inactive. It is therefore called *dextro-inositol*. Almost simultaneously, another French chemist, M. Tanret, obtained from quebracho bark (*Aspidosperma quebracho*) a sugar-like compound to which he has given the name quebrachitol. It has the same formula as β-pinitol, and on treatment with hydriodic acid yields methyl iodide and an inositol which can only be distinguished from the foregoing by its action on the plane of polarized light, which it rotates to the left to the same extent as the first compound does to the right, and must therefore represent the *lævo-inositol*. Both these compounds crystallize with two molecules of water in hemihedral crystals, and are very soluble in water.

MM. Maquenne and Tanret then jointly examined the effect of mixing concentrated solutions of equal weights of the dextro- and lævo-compound, and obtained an inactive inositol, which is much less soluble in water than either of its constituents, and melts at a higher temperature (253°), without previously becoming plastic. From its mode of formation, its constitution must resemble that of racemic acid, and the name *racemo-inositol* has therefore been given to it. It is not identical with the inactive inositol previously known, and the latter must therefore have an analogous constitution to mesotartaric acid.

We have therefore the interesting result that inositol, a derivative of hexamethylene, exists in four different forms, corresponding exactly to those of tartaric acid.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Mr. Buchanan, the University Lecturer in Geography, announces a course on "Oceanography," to begin at 2.15 p.m. on Wednesdays. The subject will be "The Distribution of Land and Water on the Globe."

The Council of the Senate have published a report in which they withdraw their original proposal (October 22, 1888) to suspend for 10 years from 1890 the augmentation of the contributions of Colleges to the Common University Fund prescribed by the present statutes, by way of relief to the depressed finances of some of the Colleges. They propose now to discriminate between Colleges that are financially depressed and those that are not. The latter will receive no relief under the new plan, the former will be allowed to make up their University contributions by devoting one or more Fellowships to University purposes. This proposal seems to have been much more widely approved than the former, and is signed by nearly all the members of the Council of the Senate.

The Special Boards for Physics and Chemistry, and for Biology and Geology, propose a new departure in the conduct of the second part of the Natural Sciences Tripos, with regard to which there are likely to be differences of opinion. Hitherto all the work considered by the examiners has been carried on at the time of the examination under their supervision, and under equal conditions for all candidates. The proposal now is to give credit for work in practical chemistry carried on before the examination in the University or College laboratories. The regulations recommended are:—

"In the second part of the examination, every candidate in chemistry may present to the examiners, at the commencement of the examination, a record of the chemical work which he has carried out in the University laboratory, or in some one of the College laboratories, in some one term. Such record shall be the original notes made from day to day in the laboratory, with the necessary calculations in full, and dated so as to show the work of each day.

"To the record shall be appended a certificate, signed by the candidate and by the superintendent of the laboratory, stating that all the manipulations involved in the work have been *bonâ fide* carried out by the candidate alone, and that the superintendent has watched the progress of the work and believes the record of it to be faithful.

In estimating the merits of the candidates, the examiners shall give credit for such work.

This regulation shall be first applicable to the examination for the Natural Sciences Tripos of the year 1892."

The Report is signed by 12 members of the two Boards, the total number of members being 31. The chemists whose names appear are Prof. Liveing, Dr. Ruhemann, and Dr. Tilden.

Mr. J. Pedrozo d'Albuquerque, B.A., Scholar of St. John's College, First Class, Natural Sciences Tripos, 1887–88, has been appointed Government Professor of Chemistry at Barbadoes.

Applications for permission to occupy the University's tables in the Zoological Station at Naples, and in the Marine Biological Laboratory at Plymouth, are to be sent to Prof. Newton, Magdalene College, Cambridge, on or before May 22.

The Newall Telescope Syndicate have issued a further Report, in which it appears that a means has been found for overcoming the threatened financial difficulty. Mr. H. F. Newall, M.A., of Trinity College, University Demonstrator of Experimental Physics, and son of the donor of the telescope, has offered his services as observer, without stipend, for five years, a sum of £500 for initial expenses, and a guarantee of £200 a year for five years for maintenance, provided the University can furnish the balance of the funds required. He also offers to build himself a private house near the new Observatory, if a suitable site can be found. The Sheepshanks Fund is, moreover, able to promise an additional sum of £100 a year after five years from the present date. The outcome of these offers is that the University will only be required to find at present a capital sum of £125, and an annual subsidy of £30. After five years, it may have to build an observer's house at a cost of £800, and provide £150 a year towards his stipend. Mr. Newall has worthily seconded his father's munificence, and it is to be hoped that no further obstacle will arise to the founding of an adequate observatory of stellar physics in Cambridge.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, March 13.—"The Nitrifying Process and its Specific Ferment." By Percy F. Frankland, Ph.D., B.Sc. (Lond.), A.R.S.M., &c., Professor of Chemistry in University College, Dundee, and Grace C. Frankland. Communicated by Prof. Thorpe, F.R.S.

The authors have been engaged during the last three years in endeavouring to isolate the nitrifying organism.

Nitrification, having been in the first instance induced in a

particular ammoniacal solution by means of a small quantity of garden soil, was carried on through twenty-four generations, a minute quantity on the point of a sterilized needle being introduced from one nitrifying solution to the other. From several of these generations, gelatine plates were poured, and the resulting colonies inoculated into identical ammoniacal solutions, to see if nitrification would ensue; but, although these experiments were repeated many times, on no occasion were they successful.

It appeared, therefore, that the nitrifying organism either refused to grow in gelatine, or that the authors had failed to find it, or that, growing in gelatine, it refused to nitrify after being passed through this medium.

Experiments were, therefore, commenced to endeavour to isolate the organism by the dilution method. For this purpose a number of series of dilutions were made by the addition to sterilized distilled water of a very small quantity of an ammoniacal solution which had nitrified. It was hoped that the attenuation would be so perfect that ultimately the nitrifying organism alone would be introduced.

After a very large number of experiments had been made in this direction, the authors at length succeeded in obtaining an attenuation consisting of about $\frac{1}{1000000}$ of the original nitrifying solution employed, which not only nitrified, but on inoculation into gelatine-peptone refused to grow, and was seen under the microscope to consist of numerous characteristic bacilli hardly longer than broad, which may be described as bacillo-cocci.

Although this bacillo coccus obstinately refuses to grow in gelatine when inoculated from these dilute media, yet in broth it produces a very characteristic though slow growth.

Nitrification was also induced in ammoniacal solutions by inoculating from such broth cultivations.

March 27.—"On the Progressive Paralysis of the Different Classes of Nerve-cells in the Superior Cervical Ganglion." By J. N. Langley, F.R.S., and W. L. Dickinson.

Summary.—Generally speaking, stimulation of the cervical sympathetic in the dog with minimal effective shocks causes pallor in the lips and gums; with weak to moderately strong shocks, primary pallor followed by flushing; with strong shocks, as shown by Dastre and Morat, primary flushing, but the extent and duration of the primary effect and of the secondary effect, if there is any, vary in different dogs.

In the rabbit and cat, stimulation of the cervical sympathetic always causes, as shown by Bochefontaine and Vulpian, primary pallor in the lips and gums, and the after-flush is not great. The pallor we find is bilateral; the degree of the pallor on the opposite side to that stimulated varies in individual cases, it can be seen in the tongue, as well as in the lips and gums.

On injecting nicotin into a vein, certain of the normally occurring effects of stimulating the cervical sympathetic cease before the others, *i.e.* since all the effects can still be produced by stimulating the fibres running from the superior cervical ganglion, the nerve-cells in the ganglion, which are connected with different classes of nerve-fibres, are paralyzed with different degrees of ease by nicotin.

Arranging the various effects in the order of ease of paralysis, we have:—

Rabbit.

(1) Withdrawal of the nictitating membrane.
(2) Opening of eye.
{ (3) Dilation of pupil.
{ (4) Constriction of blood-vessels of conjunctiva.
{ (5) Constriction of blood-vessels of lips and gums.
{ (6) Constriction of blood-vessels of ear.

In one or two cases, no difference in the ease of paralysis between the bracketed actions has been observed.

Cat.

(1) Secretion from sub-maxillary gland.
(a) { (2) Opening of eye.
(a) { (3) Dilation of pupil.
(a) { (4) Constriction of blood-vessels of conjunctiva.
(a) { (5) Constriction of blood-vessels of mouth.
(b) { (6) Constriction of blood-vessels of ear.
(b) { (7) Withdrawal of nictitating membrane.

(*a*) Constant differences between these have not been observed.

(*b*) These have not been directly compared, but in separate experiments each has been obtained when (1) to (5) were no longer seen.

Dog.

(1) Dilation of arteries of bucco-facial region.
(2) Movements of eye and opening of eyelids.
(3) Withdrawal of nictitating membrane.
(a) { (4) Constriction of the arteries of gums and lips.
(a) { (5) Dilation of pupil.
(a) { (6) Secretion from sub-maxillary gland.
(a) { (7) Constriction of blood-vessels of the sub-maxillary gland.

(*a*) Differences between these have not always been observed.

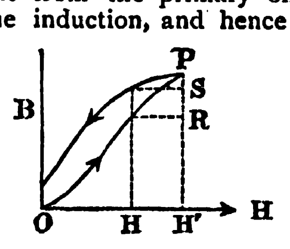
At a certain stage of nicotin poisoning, when stimulation of the sympathetic does not cause withdrawal of the nictitating membrane, but does cause dilation of the pupil, a partial *closing* of the eye is obtained by stimulating the sympathetic.

It will be noticed that in each animal nicotin abolishes most of the effects of stimulating the cervical sympathetic at very nearly the same time. With regard to these, we think that there is only a *primâ facie* case for regarding the differences observed as due to an unequal paralysis of the nerve-cells of the superior cervical ganglion, for it is possible that the differences may be due to an unequal tonic stimulation reaching the parts by nerve-fibres other than the sympathetic. But the greater differences observed, for instance, between the secretion of saliva and the dilation of the pupil in the cat, the flushing of the lips and the constriction of the vessels of the sub-maxillary gland in the dog, we do not think can be due to such a cause, and we attribute them to an unequal paralyzing action of nicotin upon the nerve-cells of the superior cervical ganglion.

Linnean Society, April 17.—Mr. Carruthers, F.R.S., President, in the chair.—Lord Arthur Russell, on behalf of the subscribers to a portrait of Sir Joseph Dalton Hooker, which had been painted at their request by Mr. Hubert Herkomer, R.A., formally presented the portrait to the Society, and in a few words expressed the satisfaction which he was sure would be felt at the acquisition of the likeness of so distinguished a botanist. It was announced that a photogravure of the portrait was in preparation, of which a copy would be presented when ready to every subscriber to the portrait fund.—Prof. P. M. Duncan, F.R.S., exhibited a vertical section through a large coral, *Fungia echinata*, cutting through and across the septa and synapticulæ and the so-called base. The union of the sides of contiguous septa at the base is either incomplete or by means of synapticulæ.—Dr. Edward Fischer, of Zurich, exhibited and made remarks on certain species of *Polyporus* bearing a sclerotium possessing the structure of *Pachyma cocos*, but it was doubtful whether the *Polyporus* represented the fructification of the *Pachyma*, or was merely parasitic on it. Mr. George Murray expressed himself in favour of the latter view.—Mr. J. E. Harting exhibited alive a so-called "singing mouse" which had been captured at Maidenhead a week previously, and which uttered sounds like the subdued warbling of a linnet. He desired to be informed whether the cause usually assigned for the phenomenon was correct—namely, some obstruction or malformation of the trachea. Prof. Stewart stated that he had observed alive, and dissected when dead, a similar specimen, and had found no trace of any organic disease or malformation.—Sir Charles Sawle, Bart., exhibited a specimen of the Little Green Heron, *Butorides virescens*, of North America, which had been shot by his keeper at Penrice, St. Austell, Cornwall, in October last, and which he had sent for preservation to a taxidermist at Bath. Mr. J. E. Harting offered some remarks on the occurrence, and suggested various ways in which the bird might have reached England. He observed that the larger American Bittern, *Botaurus lentiginosus*, had been met with some five-and-twenty or thirty times in the British Islands, and, strange to say, had been described and named by an English naturalist, and a Fellow of this Society, Colonel George Montagu (who obtained a specimen of the bird in Dorsetshire), a year before it was described by Wilson as a native of the United States.—A paper was then read by Mr. Spencer Moore, on some micro-chemical reactions of tannin. In this an account was given of the behaviour of Nessler's test for ammonia upon tannin, which it usually colours almost immediately some shade of brown or reddish brown. The great value of the reagent is held to reside in the rapidity of its action; moreover in none of the many experiments did it fail. Reference was also made to some other new tannin tests, especially to some in which, as in Nessler's fluid, caustic potash furnishes the basis, and which, like that fluid, are very rapid in their action.—A paper by Mr.

E. Saunders, on the tongue of the British Hymenoptera Anthophila, in the absence of the author was read by Mr. W. Percy Sladen, and was illustrated by excellent drawings.

Physical Society, April 18.—Prof. W. E. Ayrton, F.R.S., President, in the chair.—Prof. Rücker described the results of some recent magnetic work undertaken by himself and Prof. Thorpe in connection with their magnetic survey of the United Kingdom.—Mr. T. H. Blakesley (Hon. Secretary) read a paper, on a theory of permanent magnetism, by M. Osmond. The author stated that iron exists in two distinct physical states, one soft, or "*α iron*," and the other hard, or "*β iron*." The β variety is non-magnetic, and is formed during heating, hardening, or by electrolysis, whilst the soft or α modification is produced by long annealing. In a piece of steel the author considers the β molecules to form a rigid framework in which the α molecules become interlocked under the influence of magnetizing force, and on the degree of interlocking the permanent magnetism depends. By a graphical method it is shown that the permanent magnetism should be a maximum when the two varieties are present in equal quantities. If the proportions of carbon and manganese in the steel are considerable, then nearly all the iron is of the β variety, and the steel is nearly non-magnetic. In hardening a piece of ordinary steel, the surface layers being cooled most rapidly contain more β molecules than the interior; hence for a certain degree of hardness (when the outer layers have more α molecules than β ones) a laminated magnet will be a better permanent magnet than a solid one, but for a much greater degree of hardness the reverse may be the case. Mr. Swinburne asked if the theory would account for the increase of induction which occurs when the circuit of a permanent magnet is closed; most theories founded on the orientation of particles by the magnetizing force seemed defective in this respect. Some time ago he had suggested that the permeability of iron should be tested by first magnetizing it one way, and then at right angles to the first direction; recently he had been informed that no increase of permeability was observed when the experiment was performed. Prof. Perry said he had subjected iron to magnetization in one direction and found the permeability for small forces in a direction at right angles much smaller than he had anticipated; the first magnetizing force was kept constant when the small perpendicular one was applied. Mr. Swinburne thought that for such small perpendicular forces the permeability should be nearly infinite. He also said there seemed to be a sort of angular hysteresis in iron, for if a loose running armature was turned slowly round by hand, it would come back 2° or 3° when left free. The President remarked that, as far as he could see, M. Osmond's theory does not account for the great influence which a small percentage of tungsten has on the magnetic property of steel, and all theories which failed in this particular must necessarily be imperfect. Mr. Blakesley pointed out that the ordinary hysteresis curves showed that a small superimposed magnetizing force in a direction different from the primary one produced only a small change in the induction, and hence would give a small



permeability. For example, the increment HH′ (see diagram) causes an increase RP in the induction, whilst an equal decrement H′H produces only a change PS.

Geological Society, April 16.—J. W. Hulke, F.R.S., Vice-President, in the chair.—The following communications were read:—On the disturbed rocks of North-Western Germany, by Prof. A. von Könen, For.Corr.G.S.—On the origin of the basins of the Great Lakes of America, by Prof. J. W. Spencer, State Geologist of Georgia. From the study of the hydrography of the American lakes, from the discovery of buried channels revealed by borings, from the inspection of the glaciation of the lake region, the consideration of the late high continental elevation, and the investigation of the deformation of old water-levels, as recorded in the high-level beaches, the explanation of the origin of the basins of the Great Lakes becomes possible. The original Erie valley drained into the extreme western end of Lake Ontario—the Niagara river being modern—by a channel now partly buried beneath drift. Lake Huron, by way of Georgian Bay, was a valley continuous with that of Lake Ontario; but between these two bodies of water, for a distance of about 95 miles, it is now buried beneath hundreds of feet of drift. The old channel of this buried valley entered the Ontario basin about twenty miles east of Toronto. The northern part of Lake Michigan basin was drained into the Huron basin, as at present; whilst the southern basin of that lake emptied by a now deeply drift-filled channel into the south-western part of Huron. The buried fragments of a great ancient valley and river, and its tributaries, are connected with submerged channels in Lake Huron and Lake Ontario, thus forming the course of the ancient St. Lawrence (Laurentian) river, with a great tributary from the Erie basin and another across the southern part of the State of Michigan. This valley is of high antiquity, and was formed during times of high continental elevation, culminating not long before the Pleistocene period. The glaciation of the region is nowhere parallel with the escarpments, forming the sides of, or crossing the lakes or less prominent features. During the Pleistocene period, and especially at the close of the episode of the upper Till, the continent was greatly depressed, and extensive beaches and shore-lines were made, which are now preserved at high elevations. With the re-elevation of the continent these old water-levels have been deformed, owing to their unequal elevations. This deformation is sufficient to account for the rocky barriers at the outlets of the lakes. Some of the lakes have been formed, in part, by drift obstructing the old valley. The origin of the basins of the Great Lakes may be stated as the valley (of erosion) of the ancient St. Lawrence river and its tributaries, obstructed during and particularly at the close of the Pleistocene period, by terrestrial movements, warping the earth's crust into barriers, thus producing lake-basins, some of which had just been formed in part by drift deposited in the ancient valley. The reading of this paper was followed by a discussion, in which Dr. Hinde, Prof. Bonney, Dr. Irving, Mr. Clement Reid, Rev. E. Hill, Prof. Seeley, Mr. Whitaker, and the author took part.—On Ornithosaurian remains from the Oxford Clay of Northampton, by R. Lydekker.—Notes on a "wash-out" found in the Pleasley and Teversall Collieries, Derbyshire and Nottinghamshire, by J. C. B. Hendy.

Chemical Society, March 20.—Dr. W. J. Russell, F.R.S., President, in the chair.—Prof. J. W. Judd, F.R.S., delivered a lecture on the evidence afforded by petrographical research of the occurrence of chemical change under great pressure, in which he discussed the question as to how far the phenomena observed by the geologist in the study of rocks under the microscope can be explained by the laws that have been experimentally determined by the physicist and chemist.—The following papers were read:—The formation of triazine-derivatives, by Prof. R. Meldola, F.R.S.—Contributions to the knowledge of mucic acid; Part 1, hydromuconic acid, by Dr. S. Ruhemann and Mr. F. F. Blackman.—The molecular weights of metals when in solution, by Messrs. C. T. Heycock and F. H. Neville. The authors give the results of their observations on the effect of various proportions of silver, gold, copper, nickel, sodium, palladium, magnesium, zinc, lead, cadmium, mercury, bismuth, calcium, indium, aluminium, and antimony on the solidifying point of tin. Of all these metals, antimony alone behaves abnormally, producing a rise instead of a depression in the solidifying point. In the majority of cases the atomic depression is a number not far removed from 3, the theoretical value calculated from Van't Hoff's formula. Assuming the truth of Raoult's generalization, that the depression produced by a molecular proportion of any substance in the solidifying point of the same solvent is the same whatever the substance, it would therefore seem probable that the molecules of most metals are of the same type, M_n, where n is the number of atoms in the molecule; and if it be supposed that the molecules of zinc, for example, when dissolved in tin are monatomic as in the gaseous state, it would follow that n is unity in the case of many other metals. In the case of aluminium, the atomic depression is so nearly half the average value that it seems probable that the molecule is diatomic. Indium resembles aluminium in producing an abnormally low depression, and it is noteworthy that the value for mercury is also distinctly low.

March 27.—Annual General Meeting for the election of Officers and Council.—Dr. W. J. Russell, F.R.S., President, in the chair.—The President, in his address, discussed the teaching of chemistry to medical students, and drew attention to the

importance of the medical man being well trained in elementary chemistry, pointing out that it was too seldom recognized that the fundamental action of medicines—the origin of their power—is a chemical change, and that if an understanding and appreciation of their effects are to be sought for, the first steps must be to learn the laws which govern chemical change, and the chemical nature of the substances employed. He urged, that in place of the present unsatisfactory system, chemistry should be placed on an equal footing with anatomy, medicine, and physiology, in which subjects the Examining Board of the two Colleges insists that the student shall have studied at a recognized medical school, thus recognizing most wisely the importance of study under efficient instructors and at places properly equipped.

Paris.

Academy of Sciences, April 21.—M. Hermite, President, in the chair.—On the theory of the optical system formed by a double plane mirror in front of the object-glass of an equatorial, and movable about an axis, by MM. Lœwy and Puiseux. In a previous note (April 14) the authors dealt with the formulæ relative to the employment of one plane mirror movable about an axis. They now study the system obtained by replacing the single mirror by two reflecting surfaces cut on the same block of glass in the form of a prism.—On Weber's law of electrodynamics, by M. H. Poincaré.—On the heat of formation and reactions of hydroxylamine, by MM. Berthelot and André. One of the results of the investigation is to confirm the similarity between ammonia and hydroxylamine, their heats of formation showing only a slight difference. Hydroxylamine cannot therefore be regarded as oxidized ammonia.—On the nutrition in hysteria, by M. Bouchard. The author quotes a work by M. Empereur, "Sur la Nutrition dans l'Hystérie," published in 1876, in which demonstrations of the normal pathological state during hysteria, similar to those described by MM. Gilles de la Tourette and Cathelineau, are given.—Observations of Brooks's comet (a 1890) made with the *coudé* equatorial (35 cm. free aperture) of Lyons Observatory, by M. G. Le Cadet. On March 28 the comet appeared as an almost perfectly round nebulosity without any noticeable point of condensation. Its magnitude was estimated as 11·5.—On the actual minimum of solar activity, and the spot which appeared in March 1890 at a remarkably high latitude, by M. A. Riccò. A comparison of the number of spots that appeared in 1890 with the number observed in 1878 indicates that the minimum certainly passed towards the end of last year.—On a transformation of differential equations of the first order, by M. Paul Painlevé.—Construction for radius of curvature in certain classes of curves, notably Lamé's curves, parabolas and hyperbolas of various orders, by M. G. Fouret.—On mica condensers, by M. G. Bouty. The author finds that at ordinary temperatures, and for differences of potential from 1 to 20 volts, a thin lamina of mica opposes an absolute obstacle to the continued passage of electricity through it; also, that residual charges do not appear to depend on the penetration of electricity, so to speak, into the dielectric, but rather on a progressive increase of the dielectric constant.—On the mechanical action of alternating currents, by M. J. Borgman. In a note presented on February 3, the author described a method by means of which it was easy to produce the repulsion of conducting masses by a coil traversed by an alternating, or simply an intermittent current, discovered by Elihu Thomson. To determine the influence of various conditions on this phenomenon, the author has undertaken, and describes a series of experiments made with modified apparatus.—Halos and parhelia observed at St. Maur Park, by M. E. Renou. The relative number of halos and parhelia observed in different years and in different months of the year are given.—On one of the causes of the loss of iron ships on account of the perturbations of the magnetic needle; determination of the amount of deviation for each ship, by M. Léon Devaureix. The author has observed the deviation of the compass during six consecutive voyages from Bordeaux to La Plata, returning by Dunkirk.—Note on the preparation of iridium dioxide, by M. G. Geisenheimer. Iridium dioxide is obtained in fine brown-red microscopic needles by heating potassium iridate in a platinum crucible for an hour with 15 times its weight of a mixture of equivalent quantities of chloride and bromide of potassium. The crystals are isolated by washing first with water and then with aqua-regia. Analysis proves them to be pure IrO_2.—Action of hydrogen peroxide on the oxygen compounds of manganese; Part 1, action on the oxides, by M. A. Gorgeu. The author concludes that in the process of decomposition of hydrogen peroxide by the peroxides of manganese, the latter, especially in presence of acids, are themselves reduced to some extent if they contain more oxygen than is indicated by the formula Mn_3O_4, $\frac{1}{2}H_2O$, and that the analysis of hydrogen peroxide should not therefore be carried out by means of the hydrated higher manganese oxides.—Preparation and heat of formation of sodium erythrate, by M. de Forcrand.—Note on the chlorine derivatives of the amylamines, by M. A. Berg. Three chlorine derivatives—namely, monochloramylamine, dichloramylamine, and chlorodiamylamine—have been prepared by the action of hypochlorites on amylamine and diamylamine hydrochlorides. Analyses and descriptions of the properties of the three bodies are given.—On the alcoholic fermentation of inverted sugar, by MM. U. Gayon and E. Dubourg. Following the progress of the fermentation by means of the polarimeter, the authors show that the two components of invert-sugar are attacked with different degrees of rapidity, and that different ferments do not act in the same manner, some attacking the lævulose by preference, others the remaining component.—Note on alcoholic fermentation and the transformation of alcohol into aldehyde caused by *champignon du muguet*, by MM. Georges Linossier and Gabriel Roux.—A geological paper, by M. Stanislas Meunier, gives an account of the results of the lithological and geological examination of the meteorite from Jelica (Servia), 1889.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Studies in Evolution and Biology: A. Bodington (E. Stock).—Glimpses into Nature's Secrets: E. A. Martin (E. Stock).—A Manual of Anatomy for Senior Students: E. Owen (Longmans).—Monograph of the British Cicadæ Part 2: G. B. Buckton (Macmillan).—Fur Seal and other Fisheries of Alaska (Washington).—National Academy of Sciences, vol. 4, Part 2; 3rd Memoir—The Temperature of the Moon: S. P. Langley (Washington).—The Solar Corona: F. H. Bigelow (Washington).—Photographs of the Corona taken during the Total Eclipse of the Sun, January 1, 1889; Structure of the Corona; D. P. Todd (Washington).—National Health: B. W. Richardson (Longmans).—The Function of Labour in the Production of Wealth: A. Philip (Blackwood).—Magnetism and Electricity: W. J. Harrison and C. A. White (Blackie).

CHEMICAL TECHNOLOGY.

Chemical Technology; or Chemistry in its Applications to Arts and Manufactures. Edited by C. E. Groves, F.R.S., and W. Thorp, B.Sc. Vol. I., "Fuel and its Applications." By E. J. Mills, D.Sc., F.R.S., and F. J. Rowan, C.E. (London: Churchill, 1889.)

THIS work is described as substantially a new edition of the well-known "Chemical Technology" of Richardson and Watts, which in its turn was founded on the German work of Knapp. In its new form, however, it bears about as much resemblance to its prototype as the famous horse of Wallenstein does to the original animal—"The head, neck, legs, and part of the body have been repaired; all the rest is the real horse." How much of the real Knapp is left in the work takes some time and trouble to discover. We recognize here and there a woodcut—not always in the best state of preservation—but the descriptions appended even to these particular cuts are in most cases entirely recast, if not wholly rewritten. As the present work is to all intents and purposes an original production, it would have been better to have so described it. It may be that a sort of good-will has grown up around Richardson and Watts's "Technology" which the publishers desire to retain; but the connection between the two works is so slight that they are practically independent.

The present volume deals exclusively with fuel and its applications. The term fuel is employed in its widest possible sense, and its applications are treated of no less generally. The special employment of fuel in chemical manufactures is reserved for future treatment in the volumes which are concerned more particularly with these subjects. The most superficial comparison of this work with that upon which it is assumed to be founded will serve to show how enormous has been the advance in knowledge of the principles upon which the proper consumption of fuel depends. Take, for example, the question of smoke-prevention. In the preface to the 1856 edition it was stated that a method of smoke-prevention, although much wanted, had not then been discovered. The present work shows that we have changed all that. The idea of "consuming smoke" is obsolete. The conditions of complete combustion are to-day so well understood that it is only the indifference of manufacturers or the apathy of the authorities which prevents the greater part of industrial firing with solid fuel from being practically smokeless. Even if this were not so, gaseous fuel, the use of which is largely extending, is absolutely smokeless. This kind of fuel might be applied to many industries which have not yet adopted it, and without in any way hampering them, and would indeed be so applied if the authorities could be brought to regard it as coming within the definition of "the best practicable means" (to quote the words of the Act) for preventing smoke. We do not, of course, intend by this to insist on the exclusive adoption of gaseous fuel, although the time may come when, partly on economic and partly on sanitary grounds, such adoption may, as the late Sir C. W. Siemens predicted would be the case, become compulsory. How much the community might save, both in health and pocket, by the more systematic adoption of smoke-preventing arrangements, has been demonstrated over and over again, and we may well hope that the various exhibitions of appliances which seek to realize a consummation so devoutly to be wished may bring about this result in a not too distant future. The public may rest assured that efficient smoke-preventing appliances do exist, as the work before us abundantly demonstrates, and it ought to be the duty of the various centres of local government to insist on the more general adoption of these appliances. What can be done by a benevolent despotism in such a matter was well shown by the action of Lord Palmerston in the case of the metropolis, and there is nothing to prevent even such towns as Glasgow, Sheffield, Birmingham, and Newcastle from having atmospheres at least as sootless as that of London.

The out-put of coal in this country up to 1883 practically followed the law of Jevons as modified by Marshall. In that year it attained a maximum of nearly 164 million tons, or about four times the amount raised in 1850. In 1884 the quantity raised was 161 million tons, and in the following year it fell to about 159 millions. This diminution is due to various causes, partly natural and partly economic and social. It is, however, safe to say that a more intelligent appreciation of the principles which determine the conversion of the store of energy existing in coal into actual work has more than compensated for the smaller out-put. The world to-day gets more duty from its coal than it did even six years ago. Authorities differ slightly as to the manner in which the coal raised is distributed. According to Peckar, whose estimate seems to be preferred by the authors, it is somewhat as follows:—[1]

Destination.	Per cent.
Iron manufacture	32·40
Factories	21·87
Dwelling-houses	16·36
Gas- and water-works	6·46
Mining	6·38
Steamers	6·46
Railways	1·76
Copper-works	0·72
Sundries	0·64
Export	10·54

Although it is no necessary part of a treatise which is mainly concerned with the applications of fuel, the authors devote some considerable space to what may be termed the chemistry of coal-getting, *e.g.* the occurrence and nature of fire-damp, the relations of atmospheric temperature and pressure to its escape, fire-damp indicators, the influence of coal-dust on explosions, &c. On the whole, the information given is sound and accurate, and brought fairly well up to date. And the authors steer a very even and judicious course among points on which much difference of opinion still exists. We think, however, that the very careful and remarkable analyses of certain North Country explosions by the Messrs. Atkinson are worthy of more notice than they have apparently received, as they seem to be absolutely conclusive on the point that explosions can be originated and propagated by coal-dust alone.

[1] No explanation is given of the fact that these numbers add up to 103·59.

The question of the spontaneous ignition of coal scarcely meets with the treatment which its importance merits, and no reference is made to the work of the Royal Commission appointed in 1875 at the instigation of the Board of Trade and the Committee of Lloyd's to inquire into this subject. Many hundreds of vessels have without doubt been lost by the spontaneous ignition of coal cargoes, and there is a general belief that, with the considerable increase of temperature in steam-ships due to the introduction of high-pressure boilers and triple-expansion engines, the liability to spontaneous firing in the coal-bunkers is greatly augmented. The old idea of Berzelius, that the tendency to spontaneous ignition was mainly due to the presence of readily-oxidizable pyrites is now exploded. The experiments of Richters, Durand, and, in quite recent times, of Prof. Vivian Lewes, have shown that this substance has quite a subordinate effect. The cause is rather to be ascribed to the effect of absorbed or occluded oxygen upon finely-divided carbon, *e.g.* dust or fine slack. The authors are also of this opinion, and state that the only method of preventing fire from such a cause is to keep the temperature of the mass of coal as low as possible by means of thorough ventilation by currents of air. In a paper recently read before the Institution of Naval Architects, in which this question is discussed, Prof. Lewes comes to the conclusion that this so-called ventilation is undoubtedly one of the most prolific causes of spontaneous ignition, and he instances the cases of the four colliers, *Euxine*, *Oliver Cromwell*, *Calcutta*, and *Corah*, which were loaded at Newcastle under the same tips, at the same time, with the same coal, from the same seam. The first three were bound for Aden, and were all ventilated. The *Corah* was bound for Bombay, and was not ventilated. The three thoroughly ventilated ships were totally lost from spontaneous ignition of their cargo, whilst the *Corah* reached Bombay in safety. Prof. Lewes points out that for ventilation to do any good, cool air would have to sweep continuously and freely through every part of the cargo, a condition impossible to attain, whilst anything short of that only increases the danger, the ordinary methods of ventilation supplying about the right amount of air to create the maximum amount of heating. A steam coal absorbs twice its bulk of oxygen, and takes about ten days to do it under favourable conditions, and it is this oxygen which in the next phase of the action enters into chemical combination and causes the serious heating.

One very remarkable change which is slowly making its way in this country is seen in the more extensive adoption of coal-washing machinery. Coal-washing machines have long been in use in Germany, France, and Belgium, and the exigencies of our iron manufacture are gradually necessitating their introduction in Great Britain, although the process has not yet reached the same degree of perfection as on the Continent. The effect of washing is to free the coal from pyrites and other mineral impurities. Of course it is only under special conditions that it can pay to subject the coal of this country to this process, but there is no doubt that as soon as the price of coal touches a certain point many coals which are practically unsaleable at present will be so treated. The authors describe a number of the more important coal-washing machines, and give details of their duty and cost.

The question of coking and coke-ovens naturally comes in for a very considerable share of attention, and practically all the more important methods are described and fairly well illustrated, and the general nature of the tars yielded by the various kinds of ovens is set forth, mainly on the authority of Mr. Watson Smith. One of the most valuable features in the work is the account given of the methods of using liquid fuel, and of the results obtained on various railways (principally Russian) and with various types of marine and stationary engines. The principles of domestic heating by solid and gaseous fuel, and relative efficiency of the various forms of open and closed grates and of gas stoves, are carefully stated, and considerable space is given to an examination of the modes of warming public buildings.

Analyses of boiler performances, and of the results obtained by mechanical stokers and by the application of gas-firing to boilers, methods of evaporation, with special reference to multiple effect apparatus, occupy a large portion of the section devoted to fuel in its applications to vaporization and evaporation; and the concluding portions of the book are occupied by descriptions of special forms of kilns and furnaces.

The work is admirably printed, and on the whole well illustrated, and, what is very important in a book which is mainly a work of reference, it is furnished with an excellent index. T. E. THORPE.

THE SELKIRK RANGE.

Among the Selkirk Glaciers; being the Account of a Rough Survey in the Rocky Mountain Regions of British Columbia. By William Spotswood Green, M.A., F.R.G.S. (London: Macmillan and Co., 1890.)

THE Canadian Pacific Railway, after crossing the watershed of the Rocky Mountains by the Hector Pass, descends for some four thousand feet into the valley of the Columbia River. This, for a hundred and seventy miles, flows in a northerly direction, parallel with the crest of the range. Then, after a great sweep to the west, it flows southward, parallel to its former course, till it receives the Kootenay, the head waters of which rise only a mile and a half away from its own. The mountain-tract insulated by these rivers is called the Selkirk Mountains. It lies roughly parallel with the Rockies, and yet further west are the Gold Range and the Cascades. Thus the railway traverses a mountain region until the valley of the Frazer River, by which it finally emerges, begins to broaden out towards the sea. It is, to use Mr. Green's words, "a region of vast ravines and wide valleys, whose sides, when not bare rock precipices, are clad in sombre forests, through which wild mountain torrents rush from glacier sources to placid lakes, where, after resting for a while and reflecting the hoary cedars and hemlocks, they issue forth as great rivers, and with swift current hurry on to lose themselves in the Pacific."

Though the peaks of the Selkirks look down upon the railway, their recesses, before Mr. Green's visit, were still almost unknown. The reason is not difficult to discover. The forests which clothe their lower slopes are unusually

dense—often almost impenetrable; the traveller often has to force every step of his way among great trees, upright and prostrate, hampered by a frequent undergrowth, till the forest at last gives place to alder scrub which seems to possess all the offensive properties of the dwarf pine in the Eastern Alps, and to be a yet greater obstacle to the mountaineer. Even hunting-parties of Indians but rarely visit the Selkirks.

Mr. Green left England in the summer of 1888, with the intention of exploring and making a rough survey of the chief peaks and glaciers in the Selkirk Mountains. He was accompanied by a relative, the Rev. H. Swanzy, and took with him a mountain outfit and the requisite scientific instruments, lent by the Royal Geographical Society, who had made a grant in aid of the expense of the expedition. Convenient head-quarters were found at Glacier Hotel (4122 feet), where the trains, as at Göschenen on the St. Gothard, halt for meals; but many nights of the six weeks passed in this region were necessarily spent under canvas.

The portion of the Selkirk Range explored by Mr. Green lies mainly to the south of Rogers Pass (where the railway crosses the watershed of that range at a height of 4275 feet). It is bounded on the east by Beaver Creek, a tributary of the Columbia, and on the north by the Illecellewaet River, by which the railway descends. Many of the peaks rise above 10,000 feet; few, if any, surpass 11,000; Mount Sir Donald, which is possibly the highest, being 10,645. But the average elevation of the range is considerable, and as the peaks rise precipitously some 6000 feet above the valleys, the scenery is very fine. Though not comparable with that of the Pennine Alps, the mountain outlines are not inferior to those in some districts of the Tyrol; and the forests, where spared by the frequent fires, are far more grand. The snow-line is at about 7000 feet, the forests ending at about 6000 feet; the glaciers are numerous, and sometimes large, the most important, named the Geikie Glacier, being about 4 miles long and 1000 yards wide. As usual, old moraines and huge erratics indicate that they formerly extended far below their present limit. The Selkirk Mountains, it may be observed, correspond in latitude with the Mendip Hills.

The dominant rocks are rather fine-grained micaceous schists, the structure of which has evidently been much modified by pressure, so that it is difficult to say whether this has produced crystallization of the constituents or modified a rock once more coarsely crystalline. A snow-white quartzite or quartz-schist is also very conspicuous, and not seldom caps, and no doubt has helped to determine, the higher peaks. In one part the rocks have a yet more ancient aspect, while to the north of the railway, near some lead-mines, a black slate exhibits certain markings which may possibly be the remains of graptolites. So far as can be inferred from the specimens brought back by Mr. Green, the Selkirks are composed of either later Archæan or earlier Palæozoic rocks—probably, in great part, of the former.

That Mr. Green can use the pen as well as the pencil was proved by his former book, on "The High Alps of New Zealand." The present one deals with a more limited district, and does not include any climb equal in difficulty to that of Mount Cook; but the ascent of Mount Bonney, the second, if not the highest, peak in the Selkirks, offered more than one "bad place," and the difficulties of these excursions were enhanced by being made without guides, and in many cases only by the two travellers. Thus they not only had to be their own porters, and often carry a load of forty pounds over rough ground and up steep ascents, but also were only "two on the rope," a phrase which is significant to mountaineers. Their toils and hardships—and these were many—the physical features and natural history of the country, are all graphically described: in short, Mr. Green has written a book which not only is a record of a mountain survey carried out under exceptional difficulties, but also indicates that he possesses in an exceptional degree the qualifications for a scientific traveller, and that he can write as well as he can climb.

T. G. B.

THE ANATOMY OF THE FROG.

The Anatomy of the Frog. By Dr. Alexander Ecker, Professor of Human and Comparative Anatomy in the University of Freiburg. Translated, with numerous Annotations and Additions, by George Haslam, M.D., Scientific Assistant in the Medical Department in the University of Zürich; formerly Assistant-Lecturer in Physiology in the Owens College, Victoria University, Manchester. Illustrated with many Wood Engravings and Two Coloured Plates, executed by Hofmann, Würzburg, Bavaria. (Oxford: Clarendon Press, 1889.)

THE rapid advance of physiology and morphology since the completion of Profs. Ecker's and Wiedersheim's "Anatomie des Frosches" has intensified the desire for a text-book which should deal in the most exhaustive manner with the anatomy of the frog, "the physiological domestic animal." Dr. Haslam remarks in his preface that he has done his best to bring the original of "Ecker's Frog" up to date, and in this task he has thoroughly succeeded. More than one hundred new figures, of which one-third are original, have been added, and copious lists of references to frog literature have been drawn up. He has restricted himself to the most careful and concise description of the various organs, and has abstained from entering into the discussion of such morphological questions as bear upon the comparison of the Anura with other Vertebrata. It would therefore be out of place to criticize the retention of names which—like atlas for the first free vertebra—if applied to the frog alone, are perfectly clear in their meaning, although their true morphological value, and therefore true denomination, may possibly be different. Every anatomist knows the difficulties connected with the frog's first spinal or hypoglossal nerve; its description on p. 182 will enable the reader to form his own opinion as to which of the three or four names he may adopt.

The first section of the book, dealing with the bones and joints, has remained unaltered, but the nomenclature generally used by English anatomists has been adopted throughout. The different nature of the clavicles and the precoracoid elements has been correctly described according to investigations made since the appearance of the German original in 1864. Howes's researches on the composition of the carpus and tarsus came too late to be embodied in the English edition, but the occipito-cervical region might have been more extensively treated.

The second section, on muscles, has not been changed. Here Fuerbringer's and de Man's nomenclature might, with great advantage, have been added to, or rather given instead of, many of the antiquated synonyms of Zenker and Dugès. These, however, are points of minor importance, and are, after all, matters of opinion.

The account of the central nervous system, and that of the sympathetic system, are quite new. The same applies to the heart. Some excellent figures illustrating the anatomy of the heart have been added, or have taken the place of old illustrations. The account of the arterial system remains practically unaltered, but many additions have been made to the venous system, and the description of the lymphatics has been rearranged. Much labour has been devoted to the histology of the alimentary canal and its appendages, to a great extent based upon original research made by the translator himself. A summary tabulation of the researches on the structure of the intestinal epithelium will be found on pp. 288–290. Section VI. is devoted to the respiratory organs and the neighbouring glands. A second carefully-finished and coloured plate contains many histological drawings, mostly original, of lungs, liver, and kidneys. The histological account of the thyreoid and thymus is almost entirely new, and a pair of lymphatic glands in the hyoid region, hitherto mentioned by Tolldt only, have been rediscovered and have been described as tonsils.

"A very large number of preparations have been made to investigate the vessels and uriniferous tubes of the kidneys; and the description of the remaining organs of this section (genital organs, adrenals, and fat-bodies) has received large additions from recent publications." The description of the minute structure of the fat-bodies, with illustrations, is a new and original contribution. The eighth, or last section, treats of the skin and sense-organs. The latter were treated somewhat summarily, and meagrely illustrated, in the original edition. This defect has been amended by so many new illustrations, and by the addition to the text of the results of so much recent research, that the whole section has assumed a completely new aspect. Especially may be mentioned the structure and distribution of the peculiar tegumentary papillæ and other tactile organs. The various other sense-organs, especially the ear, and above all the eye, have received much painstaking attention, and have been amply illustrated by copies from the works of the most recent writers.

Of the 227 woodcuts we may say that they have been so carefully cut, and come out so clearly on the good paper, that the blue and red colours used for the vessels and muscles in the original edition are not at all missed. It would be going far beyond the scope of a general review to point out all the important additions and emendations which the new book contains (by the way, clearly indicated by square brackets), nor would it be fair to search for mistakes—of which, after all, there seem to be remarkably few. Those who use the work, whether for the sake of the many hundreds of references to the literature, or in order to be guided in the dissection necessary for a delicate experiment, will soon find that Dr. Haslam has greatly improved a book which was already good.

H. G.

OUR BOOK SHELF.

Syllabus of Elementary Dynamics. Part I. Linear Dynamics; with an Appendix on the Meanings of the Symbols in Physical Equations. (London: Macmillan and Co., 1890.)

THIS is a small pamphlet in which the author defines the terms usually found in works on dynamics. When dealing with measurements of quantities, he adopts an appropriate series of capital letters for specified units, and another set where the units are left undefined; thus equations containing the latter class of symbols possess more generality. Other units of higher dimensions are represented by capitals which are over-marked. Thus an acceleration of 10 feet per second per second is written as $10\bar{F}$. These are very useful for the author's purpose, though it requires no little time to become used to them. A few formulæ and results are obtained in connection with falling bodies, energy, and centre of mass.

Where quantities are represented by certain units and multipliers, it becomes necessary in every case to state any existing relations between the units employed. Instead of being under any such necessity, many physicists prefer to regard these multipliers as completely representing the quantities themselves. The advantages of such a system are discussed in the appendix, and a series of examples worked out in parallel columns, showing the advantage of the one or the other of the two methods suggested.

G. A. B.

Organic Evolution, as the Result of the Inheritance of Acquired Characters according to the Laws of Organic Growth. By Dr. G. H. Theodor Eimer. Translated by J. T. Cunningham, M.A., F.R.S.E. (London: Macmillan and Co., 1890.)

THE work of which this is a translation we have already reviewed. The only additional matter contributed by the translator seems to be an ill-advised reference to NATURE in the preface.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Bison not Aurochs.

IN his excellent article on the extermination of the American bison, "R. L." remarks (NATURE, p. 11) on the transatlantic practice of miscalling that animal a "buffalo"; but on the next page he writes of "its European congener the Lithuanian aurochs." This is to perpetuate a common error at least as bad. The "aurochs" (= ox of yore), Latinized by Cæsar in the form *urus*, is or was the *Bos primigenius* or *B. urus* of scientific nomenclature. It is wholly by mistake that in its extinction as a wild animal its ancient name was transferred to the bison, or *Zubr*. I would invite "R. L." to turn to the word "Bison" in Dr. Murray's "New English Dictionary," where he will find a reference to an article "*Wisunt*" in Schade's "Altdeutsches Wörterbuch," which ought to settle the question. I only wish one could ascertain to what animal the name "buffalo" strictly belongs. There unfortunately Dr. Murray does not help us.

ALFRED NEWTON.

Magdalene College, Cambridge, May 4.

Unstable Adjustments as affected by Isolation.

IN a brief passage in his very suggestive volume on "Darwinism," Mr. Wallace refers to a principle which seems to me to be worthy of much wider application than he has given. It is a key which requires only a little filing to prepare it for unlocking some difficult problems in divergent evolution. Speaking of the infertility of crosses, he says:—"It appears as if

fertility depended on such delicate adjustment of the male and female elements to each other that, unless constantly kept up by the preservation of the most fertile individuals, sterility is always ready to arise. . . . So long as a species remains undivided, and in occupation of a continuous area, its fertility is kept up by natural selection; but the moment it becomes separated, either by geographical or selective isolation or by diversity of station or of habits, then, while each portion must be kept fertile *inter se*, there is nothing to prevent infertility arising between the two separated portions" (p. 184). Here is an application of the principle of segregation, or of like to like in groups that do not cross, in which indiscriminate separation is followed by increasing divergence in the different portions, not because they are exposed to different environments, not because there is any advantage in such divergence, not because there is any need that the function should be performed more perfectly in one portion than in the other, but because intergeneration, which is the principle by which correspondence of function is secured, has been suspended for some generations; and, in the absence of intergeneration, neither natural selection nor any other principle is capable of preserving complete correspondence. In organisms that reproduce sexually, the causes of divergence are many, though they may all be classed as causes of segregation, while the causes of correspondence with variation, whether of functions or of structures, are causes of intergeneration between partial segregations. If the environments surrounding the isolated portions are the same, the *use* of the environment, and therefore the forms of natural selection, may become divergent; if the use continues unchanged, some *useless divergence in the method of securing the use* may appear. Or, if all the relations to the environment, whether useful or useless, remain unchanged, "the adjustment of the male and female elements to each other" are liable to become slightly divergent, producing *mutual infertility*. Or the *preference of the sexes* for certain shades or arrangements of colour in their mates may become slightly different. Through some slight difference in the hereditary elements, distributed in each separated portion at the first, one or all of these causes of accumulated divergence may be introduced. I think it is evident that we have here a general principle, which is as applicable to a wide range of divergences as it is to the divergence that produces mutual infertility and sterility.

The context shows that the prominent idea in Mr. Wallace's mind was divergence in the adjustment of the male and female elements through correlation with "some diversity of form or colour," resulting from divergent forms of natural selection, that had been induced by exposure to "somewhat different conditions of life." But if the reasoning is correct in the sentences I have quoted, it gives an explanation of similar divergences when the separated portions are exposed to the same environment, *and where there is no possible advantage to be gained by divergence*. This is one of the principles I have used in the explanation of the divergences of Sandwich Island land mollusks; and I think that in the earlier stages of the development of infertility between allied forms it is often the only explanation that is applicable. It should, however, be remembered that, for divergence of this kind, it is not always necessary that the isolation should be either complete or very long continued, and that, when the forms that are not fully fertile with each other meet and more or less commingle, there is, through the very laws of propagation, without any aid from natural selection, a constant increase in the ratio of the pure breeds to the mongrels, and an accumulating intensity in the segregative instincts and the physiological incompatibilities. As this point has been fully discussed in my paper on "Divergent Evolution," I do not need to enlarge on it here (see Linn. Soc. Journ., Zoology, vol. xx. pp. 246–72).

There is, however, another phase of the subject which is indicated by Mr. Wallace's suggestion that infertility depends on "such a delicate adjustment" that it is more easily affected by isolation than some other adjustments. This is, I think, a very interesting point, as it suggests how it is that, in some cases at least, physiological divergence of this kind *is one of the first forms of divergence that arises*. But in some species other adjustments seem to be more delicate than this, and therefore more easily disturbed; while in others, several sets of adjustments, as colours and other recognition marks, with the preferences that correspond, and the habits of feeding and defence are in a state of equilibrium, the stability or instability of which is about the same as of that which determines the relations of the male and female elements. In this last class of cases, several forms of divergence may arise during the same stage of development, and that too when the isolated portions are exposed to the same environment. In some species a large number of characters are in a state of unstable adjustment. As Prof. Lankester has suggested near the close of his review of Mr. Wallace's book, this cause of divergence seems to be specially operative in the case of human faculties. But variability with plasticity of type is not the only condition that affects the stability of segregated portions of a species. Other things being equal, a single pair of any species is much less likely to represent the average of all the characters of the species than a million pairs. This consideration throws light on the comparative lack of divergence between the land animals of England and those of Ireland, which lack has been referred to by Mr. Wallace as an objection to my theory. In this case, many millions of some of the species were probably existing in each district at the time of the separation. As Prof. Lankester has pointed out, the representatives of the human species in the two districts have somewhat diverged; and the probability is, that if we were equally acquainted with the other species, we should find other examples of divergence in minor points. If the isolation is made more complete, and is longer continued, I believe the divergence will gradually become more apparent.

Mr. Wallace has mentioned another class of divergences which are best explained by the principle we are now considering—as he seems to have apprehended, though the process is not stated here as clearly as when discussing the divergences that produce infertility. The passage is as follows:—"The enormously lengthened plumes of the bird of paradise and of the peacock must be rather injurious than beneficial in the birds' ordinary life. The fact that they have been developed to so great an extent in a few species is an indication of such perfect adaptation to the conditions of existence, such complete success in the battle of life, that there is, in the adult male at all events, *a surplus of strength, vitality, and growth-power which is able to expend itself in this way without injury*. That such is the case is shown by the great abundance of most of the species which possess *these wonderful superfluities of plumage*. . . . Why, in allied species, the development of accessory plumes has taken different forms, we are unable to say, except that it may be due to that individual variability, which has served as the starting-point for so much that seems to us strange in form, or fantastic in colour, both in the animal and vegetable world" ("Darwinism," p. 293. The italics are mine).

It is no small gratification to me that Mr. Wallace has found this principle of unstable adjustment worthy of application to two important classes of divergences; and that, in the case of one of these classes, he has recognized that correspondence in such adjustments cannot be continuously maintained between the isolated portions of a species. I, moreover, have some hope that, when he understands the relation in which instability and isolation stand to each other in my theory, he will admit that it throws some light on the remarkable divergences of Sandwich Island land mollusks. The subject was only incidentally touched upon in my paper on "Divergent Evolution through Cumulative Segregation," but will be more fully discussed in a supplemental paper on "Intensive Segregation."

26 Concession, Osaka, Japan. John T. Gulick.

Coral Reefs, Fossil and Recent.

Many Alpine geologists believe the limestone and dolomite mountains which form so peculiarly beautiful and interesting a part of our Eastern Alps to be in great part composed of Triassic coral reefs. If this be so, their geological structure must necessarily contribute much towards elucidating the discussion concerning the origin of atolls and other forms of recent coral reefs. In this discussion, which has chiefly been carried on in England, the structure of our Triassic limestone mountains has been left out of account in a manner very surprising to me, considering that authorities like Richthofen and Mojsisovics have declared them to be remnants of coral reefs.

I have made a number of Alpine ascents in the dolomites of South Tyrol, chiefly in the districts of the Höhlensteinthal, Primiero, and the Langkofel, and have satisfied myself that the theory of the coralligenous origin of great part of these mountains is the only one which will explain the position and nature of the rocks composing them.

Not only do we observe in many places the massy dolomite alternating at its margin with sedimentary deep-sea deposit of

partly non-calcareous nature, but we even find old reef surfaces exposed to view. The volcanic porphyritic lava, or rather tufa, which was spread over the sea-bottom after the termination of the Buchensteiner period (middle Triassic, Mediterranean province) covers the deep-sea deposits of earlier date, but leaves the masses of dolomite free. Here and there, as on the *Plattkofel*, it can be seen overlying the foot of the actual reef precipice and there ending. It is covered by similar dolomite of a later date.

Many observations by Dana, Walther (" Korallriffe des Rothen Meeres"), and others, have shown that old coral reefs, about the nature of which there can be no doubt, are often dolomitic. The structure of Tertiary coral reefs on the Sinai peninsula, about the origin of which no doubt can be entertained, is actually identical with the structure of some Triassic dolomite I have examined here. I believe myself, for these, and many other reasons, justified in agreeing with Richthofen, &c., and in assuming that many Tyrolese Triassic limestones and dolomites are coralligenous.

The zones of the Mediterranean Trias differ altogether from the Trias in Germany. Other limits must here be recognized. In this respect I follow Mojsisovics. In the lowest Triassic no coral reefs are observed; also in the zones corresponding to the German Muschelkalk, we find, although these deposits are usually calcareous, no reefs of any size. It is in the zones distinguished as Buchensteiner, Wengener, and Cassianer-Schichten, that the great massy, unstratified reefs of South Tyrol are met with. The Upper Triassic layers, known as Raiblerschichten and Dachsteinkalk, are in South Tyrol mostly stratified, and in my opinion sedimentary, not coralligenous. Numerous faults traverse South Tyrol and break up the whole, only slightly folded Triassic system, into numerous plates (*Tafeln*) which are elevated on one (usually the northern) and depressed on the other (usually the southern) side. Liassic, Jurassic, and even Cretaceous layers rest on the depressed margins of the plates. Elsewhere these have been entirely removed, and the underlying Triassic reefs, capped with remains of sedimentary Dachsteinkalk and Raiblerschichten, have been laid bare. On the elevated margins along the faults also the Triassic layers have been removed. It is clear that somewhere between the subsided margin of the plates covered with Jurassic deposit, and the elevated margin, laid bare down to the Dyas, there must be places where the erosion has just reached the middle Triassic reefs. Here it is that we find parts of natural reef surfaces exposed.

The Lower Triassic Werfener Schichten are divided from the middle Triassic by deposits of gypsum, which show that the sea receded after the Werfener Schichten had been formed. Afterwards the sea returned, and it is clear that it must have risen at least as high as the later layers are thick, whilst or before they were deposited. The fossils in the sedimentary deposits between the masses of structureless dolomite show that the depth increased during their deposition. These sedimentary deposits alternate, as above stated, at their margins with the dolomite at the foot of the reef precipices. Therefore the dolomite also was formed during the rise of the water, for which I shall henceforth use the more exact expression introduced by Suess—positive shifting of the coast-line.

The dolomite masses are coral reefs. They have been formed during a period of positive shifting of coast-line, therefore we may assume that the high coral reefs now living and growing may have attained their astonishing altitude over the sea-bottom during a period of positive coast-line shifting. The dolomite masses of the Wengener and Cassianer period show no trace of stratification, such as is observed in the lower Muschelkalk and in the higher Dachsteinkalk. Moreover the dolomite has the same perfectly uniform structure from top to bottom; and on the vertical cliffs produced by erosion, which are often several thousand feet high, no trace of a stratified basal part can be detected. Everywhere the massy dolomite rests on discordant older layers, or—as usually at the reef margin—on the simultaneously deposited deep-sea sediment.

I will now proceed to utilize the facts here outlined in criticizing the discussion between the advocates of Darwin's and Dr. Murray's theories concerning the origin of coral reefs. I may say at once that all the phenomena observed in the dolomites of South Tyrol corroborate Darwin's subsidence theory, whereas they do not find explanation if we accept Dr. Murray's. It is the latter, therefore, which requires a closer examination.

Dr. Murray says that on slight elevations of the sea-bottom calcareous sediment accumulates, whereas in the greater surrounding depths this is not the case in consequence of the increase of dissolving power of sea-water with increasing depth. I accept this, and I believe that the caps of stratified Dachsteinkalk on the summits of many of the middle Triassic reefs in South Tyrol have been formed in this manner after the growth of the reefs had terminated. The positive coast-line shifting led to a horizontal extension of the Triassic Mediterranean northward, and a junction with colder northern seas, which caused a cooling of the water in the bay of South Tyrol, and thereby terminated the existence of reef-building corals. The positive coast-line shifting continued, and during its progress the Dachsteinkalk was deposited on the summits of the reefs, whilst the intermediate deeper spaces were left free from calcareous deposit—in accordance with Dr. Murray's view. There is, however, as above stated, nowhere a trace of stratified calcareous sediment forming a *basement* or nucleus to any one of the dolomite masses.

Dr. Murray then goes on to say that, as soon as the accumulating calcareous sediment has reached the region of coral growth, say the 20-fathom line, corals will grow on it, and an isolated atoll rising precipitously, perhaps ten thousand feet from the sea-bottom, will be formed. Against this it must be objected that the soft Globigerina ooze, which forms the whole of the atoll-peak, with the exception of an insignificant coral cap, could never attain such precipitous slopes as the atolls usually have. A slope of 45° or more could never be formed. The fossil deposits of this kind observed in South Tyrol (*Uebergussschichten* of Mojsisovics) nowhere terminate abruptly like the reefs. Neither is a slope of this kind anywhere observed in the region of the Dachsteinkalk.

Then, according to Dr. Murray, an atoll is formed by the solution of the lime in the centre of the reef. Although the Oolithes discovered in reef regions by Walther show clearly enough that there cannot be any solution other than what is compensated by redeposition, in any enclosed lagoon, I would like to draw attention to the logical discrepancy in this part of Dr. Murray's theory. First, a limestone cone is built, because the lime is deposited more rapidly than it can be dissolved. Then a lagoon is formed because the solution exceeds the accumulation, and this on the same spot, in still shallower and less powerfully dissolving water, and in spite of the relative stagnancy of the water in the lagoon and the limestone material, which is continually washed into the lagoon from the parts of the surrounding reef, which lie above the level of the sea. I think that gives the *coup de grâce* to Dr. Murray's atoll theory.

There remains yet something to be said on his ideas concerning the lateral growth of reefs. There can be no doubt that there is such lateral growth, and that the band of living coral on the reef margin can advance towards deeper water on a basis of coral fragments which have fallen from the outward growing face of the reef. As the corals near the surface grow more rapidly than those further down, the advancing reef face must ever tend to become overhanging; parts of the living coral must therefore frequently break off, fall down, and accumulate below. But there is a limit to this lateral growth which restricts it so considerably that it will by no means explain the formation of masses of dolomite 4000 feet thick, like the Cimon della Pala, for instance; and far less will it enable an atoll rising 10,000 feet or more from the bottom of the sea to extend horizontally. The amount of material *available* for the formation of a basis whereon the laterally growing corals may find footing is limited, and grows only in proportion to the circumference of a reef. The amount of material *required* for this purpose grows in a much more rapid proportion because it has to cover the surface of the growing cone.

Take a simple case. An ordinary straight fringing reef advances on a bottom of 10° inclination straight outward. At a distance of 280 metres from the shore a depth of 50 metres is reached. Further lateral growth is only possible on a talus of coral *débris*. 560 metres from the shore the depth is 100 metres. If the talus will lie at an angle of 45°, an amount of 50 cubic metres extended over a surface of 71 square metres will be necessary for the advance of each 1 metre's length of reef a distance of 1 metre. This talus is contributed from 50 square metres of growing coral (vertical reef face). At a distance of 5600 metres from the shore the depth will be 1000 metres. Every 50 square metres of growing reef face will have to furnish 950 cubic metres of material to enable the reef to advance 1 metre. These 950 cubic metres will be distributed over a surface of 1350 square metres. In

other words, the reef will advance nineteen times as slowly as it does 560 metres from the shore, whilst the surface which is exposed to the dissolving effect of the sea-water has also increased nineteen-fold. Where an ocean-current strikes such an incline, no Globigerina ooze can be deposited on it, and here the dissolving action of sea-water will balance the accumulation of coral *débris* long before such a height—of 1000 metres—is attained. It is clear that as soon as such equilibrium is reached there is a limit to the further extension of the reef in that direction. On the opposite side, however, where ooze will accumulate and protect the advancing reef from solution, such advance would be possible, but on that side the growth of coral is notoriously slow. Certainly, when the foot of the reef has advanced to depths below the zone of protecting Globigerina ooze no further lateral growth in *any* direction will be possible, and on the whole I should not think that lateral growth can play any considerable part in the formation of great reefs. Only positive coast-line shifting has such a result. In places where there is no such coast-line shifting (Gulf of Suez) the reefs are exceedingly small and insignificant.

Although therefore lateral growth no doubt does take place, it is not the actual cause of the formation of the great coral reefs.

We must, I think, revert to Darwin's subsidence theory, which is equally proved by the untenability of the hypothesis suggested for the purpose of superseding it, and by the direct evidence of the structure of the Triassic reefs in the Eastern Alps, which have actually attained their immense thickness during a period of positive shifting of the coast-line. R. von Lendenfeld.

Innsbruck.

Slugs and Thorns.

In Nature, vol. xli. p. 393, I pointed out that thorns might not always be a protection from snails and slugs, since they were found in the stomach of a European slug, *Parmacella*. In further confirmation of this view, I have to-day dissected a number of sharp, straight, reddish-brown thorns, over a millimetre long, from the intestinal tract of *Ariolimax niger*, var. nov. *maculatus*, a slug of rather doubtful affinities (possibly referable to *A. andersoni*), received from Dr. J. G. Cooper, who found it under drift-wood at Haywards, California. It is curious that the thorns do not pierce the intestine, but they appear to cause no inconvenience. T. D. A. Cockerell.

West Cliff, Colorado, April 21.

COMETS OF SHORT PERIOD.

It is now generally accepted that the periodic comets of our system did not originate in it, but are bodies captured from outer space by one of the planets, the parabolic orbits in which they approached the system being transformed into elliptical ones. On account of the perturbing action of Jupiter, however, the orbits of short-period comets are liable to considerable modifications, and it is practically impossible to identify two apparitions of the same comet without laborious computations of the perturbations which it must have been subjected to between the two epochs. But even such computations may lead to a negative result, for frequently comets quite distinct have elements very much alike, probably because they are parts of an old comet travelling along the same orbit at greater or less intervals.

In some recent investigations on the capture theory of comets (*Bulletin Astronomique*, June and July 1889), M. Tisserand developed a relation that might be employed to determine the possibility of identity of comets whose elliptical elements are known. This criterion depends upon the fact that the velocity of a body revolving round a central one is the same for equal radius-vectors. In the case of a comet having a parabolic orbit coming under the influence of a planet, the latter plays the part of the central body, and the relative velocity of the comet with reference to it will be the same at the point of entry into the sphere of attraction as at the point of departure from it, the one point being in the old orbit, the other in the new one. If two comets are identical, their velocities with reference to the perturbing planet will be the same at these points.[1]

M. L. Schulhof has discussed the possibility of identity of several comets by means of M. Tisserand's formula (*Bull. Astr.*, November and December 1889, and *Astr. Nach.*, 2964), and the following tables contain the values of n found for those having periods from 3·3 to 8·8 years. In the first table, the comets whose periods are well known are given; in the second, those having uncertain periods. Comets which have undergone strong perturbations since discovery, and those for which perturbations prior to the first known apparition have been calculated, are given more than once, and the year indicated for which the elements are found. The symbols used have their usual signification, and l is the longitude of the comet at the point of nearest approach to Jupiter.

The value of n therefore found by the formula given is almost constant for the 21 known short-period comets, being contained within the limits 0·41 for Denning's comet, and 0·59 for Encke's and Tempel's comets.

It will also be seen that only five comets have their minimum distance to Jupiter's orbit between $l = 284°$ and $l = 112°$, while twelve have the point of nearest approach between $l = 153°$ and $l = 233°$. This unequal distribution along the ecliptic cannot be accidental, and

[1] M. Tisserand expressed the criterion very approximately by the formula—

$$\frac{1}{a_1} - \frac{1}{a_2} = \frac{2\sqrt{A}}{R^3}(\cos i_2\sqrt{p_2} - \cos i_1\sqrt{p_1}),$$

where a_1, a_2, p_1, p_2, i_1, i_2, are the semi-major axes, parameters, and inclinations of the old and new orbits; A and R the planet's semi-major axis and radius-vector at the point of nearest appr.ach. This relation may be divided up into two parts, having the form—

$$n = \frac{1}{a} + \frac{2\sqrt{A}}{R}\cos i\sqrt{p}.$$

is in favour of the capture of comets by Jupiter. In fact, the accumulation of these points about $l = 192°$, which is the longitude of Jupiter's aphelion, may be partially explained by the circumstance that at this point Jupiter as well as the comets move more slowly than at perihelion, hence the sphere of attraction of the planet is sensibly extended, and its action exercised for a longer time on bodies moving in its neighbourhood.

The similarity of the elements of many comets is very manifest from the above tables, and M. Schulhof discusses in detail the probable identity of such. During last year Mr. Chandler brought forward evidence that Brooks's comet, V. 1889, was identical with the celebrated lost comet of Lexell, and the latter comet has also been asserted to be identical with that of Finlay, VII. 1886, to which it presents many points of resemblance. It is shown in the discussion that, by computing the orbit of Brooks's comet before 1886, the question of its identity with that of Lexell may be settled, while an extended calculation of the perturbations undergone by Finlay's comet indicates that it could not have been near Jupiter in 1779, and hence it is probably not identical with Lexell's comet. The elements of Finlay's comet are also very similar to those of Vico's comet, I. 1844. In order that the two may be identical, it is necessary that Mars should have augmented the period of Vico's comet by almost two years between 1844 and 1886.

The elements of Denning's comet present a certain analogy with Pigott's comet, but the two are shown to be certainly distinct.

Blainpain's comet, 1819, and that of Grischau, 1743, are most probably identical, and the elements of both these present a strong analogy with those of Tempel's comet, so that it is not impossible that this last comet is identical with the other two, or at least with Grischau's comet.

Whether Coggia's comet, VII. 1873, is identical with Pons's comet, I. 1818, is not settled. It is interesting to remark, however, that the value of $n_j = 0·484$, corresponding to a period of 5·67 years for Pons's comet, is exactly equal to that of Biela's comet. This, therefore, appears to confirm the opinion that both Biela's comet and that of Coggia represent the *débris* of an old comet, for, in the case of the division of the materials forming a comet, n_j may be regarded as constant for each of the portions detached.

To decide the question of the identity of Winnecke's with Helfenzrieda's comet, the perturbations undergone by the former towards 1800, when it approached very near to Jupiter, have been found, and it is shown that for the identity to be possible it must have moved faster in its orbit before 1800 than it does now—that is, the period must have been shorter.

This discussion of cometary identities, coupled with M. Tisserand's elaborate investigations, supports strongly Laplace's hypothesis that comets coming from stellar space, and moving in parabolic orbits, only become periodic by the perturbing action of one of the planets. This theory best explains the origin of the families of comets that cluster round the major planets, and the well-established fact of the disintegration of certain periodic comets, as Biela's in 1846, and Brooks's in 1889. Indeed, such disintegration must eventually happen to all periodic comets. RICHARD A. GREGORY.

THE JOURNAL OF MORPHOLOGY.[1]

THE issues before us constitute the first three parts of the third volume of this excellent journal. They contain 502 pages with numerous plates and a vast number of woodcuts. The chief contribution in the June number is that of Dr. Macmurrich, on "The Actinaria of the Bahama Islands." The author's material was collected during the summer of 1887, in connection with the work of the marine zoological station of the Johns Hopkins University. The monograph forms a very valuable contribution to the literature of the Actiniæ, and it may be regarded as a first step towards a rational comprehension of the tropical members of this group. It is the more welcome to us at the present juncture, in view of the revision of our native Actiniæ now progressing, in the hands of Haddon and his pupils; and we cannot but regard the excellent results obtained by Macmurrich as furnishing an additional argument in favour of the advantages of a peripatetic University marine laboratory, as compared with one of fixed habitat. Fourteen species are described, of which three are new, The illustrations are particularly good, and the following distributional conclusion is arrived at, viz. that

"so far as the Actinaria are concerned two great areas of distribution can be defined,—the Indo-Pacific, including the Indian and Pacific Oceans and the seas connected with them, such as the Red Sea; and the Atlantic, including in this the Mediterranean. The Caribbean region of the Atlantic is, however, to be separated from the Atlantic region and united with the Indo-Pacific, the relationships of its Actinaria being very certainly with those of that region."

Of the remaining papers in the first part, two are by Dr. R. W. Shufeldt, and they treat respectively of "The Comparative Osteology of the Families of the North American Passeres," and of "The Anatomy of *Speotyto cunicularia hypogæa*." Both communications are written and illustrated in that peculiar style for which their author is notorious. In the first-named paper the author reverts to his recently expressed belief in a near kinship between the swifts and swallows, but he adds nothing of fresh interest in this debated question. His papers bear the mark of honest work, and we wish them a favourable reception.

The last communication is one of 8-9 pages upon the "Variation of the Spinal Nerves in the Caudal Region of the Domestic Pigeon," by J. I. Peck. Although short, it is the outcome of a laborious investigation instituted to ascertain whether the spinal nerves vary in the same ratio as the caudal vertebræ, "or whether they remain constant in number and position of exit from the vertebral canal, without reference to the number of vertebræ themselves." One very interesting result of the author's investigation is the discovery that the coccyx does not diminish in length proportionate to the increase in number of the free caudal vertebræ—on the contrary, it is longest where the said vertebræ are most numerous; therefore, the detachment of the supernumerary vertebræ from the pygostyle would appear to be due to influences at first productive of a lengthening of the entire caudal region. The interest of this topic is vastly increased, on reflection that the assiduity of a Parker has shown us that our swans and ducklings are the bearers of a tail potentially longer than that of the Saururian, Archæopteryx.

In the September issue there are two papers, and each is a valuable monograph of its kind. That which will command most attention is the thesis by Prof. Cope upon "The Mechanical Causes of the Development of the Hard Parts of the Mammalia." To this subject there are devoted 150 pages, 5 plates, and close upon 100 most admirable woodcuts.[1] The paper is, for the most part, an elaborated *résumé* of the author's earlier and scattered contributions upon the subject under discussion; and with

[1] *The Journal of Morphology*, June to December 1889. (Boston: Ginn and Co.)

[1] We wish we could see this author's voluminous treatises invariably illustrated in a manner similarly befitting their contents. We cannot refrain from comparing the one under review with that on the "Batrachia of North America" recently published under the auspices of the United States National Museum. The illustrations in this are as poor as those referred to above are excellent: carelessly drawn, badly planned, miserably lettered, and in places misleading (if not inaccurate), they "illustrate though they hardly adorn" the text to which they are appended, while they render a large portion of the same of little or no avail for working purposes.

these he has incorporated the allied work and generalizations of Ryder and other collaborateurs, the whole being woven into a connected argument. The author declares at the outset that he is the more convinced "that it is the habit that has given rise to the structures of animals, and not the structures which have forced animals to adopt their special habits," while he sets himself to discover, "in the light of the descent traced by palæontology, the mechanical causes for the existence of the salient characters of the skeleton and dentition of the Mammalia." The paper abounds in suggestive and ingenious passages, and the author sums up his conclusions in the words:—

"The general law which we may derive from the preceding evidence is, that in biological growth, as in ordinary mechanics, identical causes produce identical results."

We have, in all, that which savours of rank Lamarckism; and the assiduous author of the remarks we have cited is (as our readers have lately been made aware), clearly, no believer in the non-transmission of acquired characters. He asserts that

"since the modifications acquired by use during life are necessarily useful, it seems that, according to the post-Darwinians, the only way of acquiring useful variations known to us, is excluded from the process of organic evolution;"

and further, that

"were this hypothesis true, there would have been no evolution."

Again, he writes,

"in spite of Weismann's theory to the contrary, so long as the germ-plasma is subject to nutrition, it is subject to influences during the adult life of an animal, and it would be an exception to all other tissues were it not so."

The second and last paper in the September issue is by W. M. Wheeler, upon "The Embryology of *Blatta germanica* and *Doryphora decemlineata*." It is illustrated by seven exquisite plates, which, we are glad to note, are of native (American) origin. In testimony to the thoroughness of the author's work, it need only be said that he professes to be able to tell "just what position any oöthecal egg held in the ovary, or just what position any egg in the ovary will hold in the capsule." Evidence of direct cell-division is adduced, and the author's observations under this head have a most important bearing upon the allied researches of Carnoy. The author records the discovery of the very early appearance and paired arrangement of the Malpighian tubes, and he regards the facts to which he alludes as indicating "that at one time they opened on the surface of the body, and that their orifices were subsequently carried in by a deepening of the proctodæal invagination," and that "probably these tubes in insects are homologous with the anal tubes of *Echiurus* larva, which are modified segmental organs." Gegenbaur, as is well known, long ago postulated such an origin for the excretory apparatus of the Insecta, and Beddard has lately substantiated his belief, on argument from analogy to the Chætopod worms, in which he finds (*Acanthodrilus*) evidences of such an inturning of undoubted nephridia. The author has investigated, among other things, the orientation in oökinesis, and he draws the conclusion that "the force of gravitation has no perceptible effect on the development of the eggs of *Blatta*, but that these highly differentiated eggs, utterly unable to revolve in their envelopes, like the eggs of birds and frogs, have their constituents prearranged, and the paths of their nuclei predetermined, with reference to the parts of the embryo."

In the December number of the journal, Dr. Shufeldt communicates a detailed work "On the Position of *Chamæa* in the System" (28 pp.). In this welcome addition to his previous papers on the smaller Passerines, the author gives a short description of the pterylosis, visceral anatomy, and myology of the bird, and deals at greater length with its skeletal anatomy; he concludes that the Wren Tit is allied to the Bush Tits (*Psaltriparus*) rather than to the true Wrens. Dr. G. Baur rushes into print with two short notes, "On the Morphology of the Vertebrate Skull," and "On the Morphology of Ribs and the Fate of the Actinosts of the Median Fins of Fishes," respectively. In the twelve short pages devoted to the two, the conclusions are arrived at that "the doctrine of the 'otic' bones established by Prof. Huxley twenty-five years ago, and held since that time by nearly all morphologists, is incorrect," and that "the elements of the anal and caudal fins of fishes . . . are represented by the chevron bones of the tail vertebræ, which are the partial homologues of the actinosts." The author's proposal to revive the term "petrosal" for that element now known as the "pro-otic" is especially to be deplored. These notes, although not wholly destitute of merit, are premature. They deal with questions in morphology which have taxed the powers of the greatest anatomists, and which are not to be summarily disposed of in a succession of scrappy communications, any one of which may more or less completely contradict its predecessors. If, in respect to these leading topics, every intelligent inquirer is thus to dogmatically foist upon the public his musings upon facts observed in individual specimens, to say nothing of others pitchforked in second-hand, and which he has therefore not observed at all, what is to become of our already too voluminous literature? We cannot allow to pass unnoticed the contraction of Theromorpha to "Theromora"; life is too short for actions of this kind, even if etymologically justifiable. The remaining contribution is by E. B. Wilson, upon "The Embryology of the Earthworm" (55 pp.). It is an extended account of investigations previously announced in an earlier issue of the same journal; and it is, moreover, very welcome now that current research is revealing in the earthworms an altogether unexpected and intensely interesting range of modification. The author's results raise momentous questions affecting the most important of current morphological beliefs; while largely confirmatory of the recent work of Kleinenberg, they run counter to the same in matters of vital importance, and interest in them is thereby enhanced. The most important topics dealt with are the origin of the mesoblast and the development and morphology of the head (prostomium). The author asserts that Kleinenberg was in error in his account of the origin of the first-named, and he criticizes those facts and deductions which lead him to reject the ordinary conception of the mesoblast as an embryonic layer: he attempts to show that the cerebral ganglia do not arise independently of the rest of the nervous system, and that the cavity of the prostomium is from the first unpaired. These and other lines of investigation have led him to a reconsideration of the annelid Trochosphere, and that he regards as "a secondary larval form," which has "arisen from an elongated segmented ancestral form, . . . the head region or prostomium being enormously developed, . . . and the trunk region more or less reduced." The author confirms Kleinenberg's discovery of the remarkable "cleavage-pore," and suggests a probable significance for the same. He regards both muscular and glandular segments of the nephridia as ectoblastic in origin, and he adduces reason for suspecting that the Hirudinea may formerly have possessed setæ. The last-named is by no means the least suggestive point raised in this excellent paper, which fully realizes the expectations raised by its author in his preliminary note referred to.

We observe that the late publication of this journal, so conspicuous at the outset, is being persisted in. With respect to this, as concerning more than one of their scientific serials, our American brethren are establishing a dangerous precedent for which there is absolutely no excuse; and it is with much dissatisfaction that we note the adoption of a similar course nearer home.

G. B. H.

NOTES.

THE first *conversazione* of the Royal Society will be held at the Society's Rooms, Burlington House, on Wednesday next, May 14.

THE Royal Geographical Society is to be congratulated on the brilliant reception accorded under its auspices to Mr. Stanley at the Albert Hall on Monday. All the arrangements had been made with the greatest care, and the proceedings were in every way most successful. No one who was fortunate enough to be present could fail to see how fully the English people recognize, and how warmly they appreciate, Mr. Stanley's achievements.

THE Chancellor of the Exchequer will receive a deputation on May 15 from the Marine Biological Association of the United Kingdom in reference to the Treasury grant in aid of that Society's investigations of the natural history of marine food-fishes. A large monograph on the common sole, illustrated by many coloured plates, will be among the evidences of work done which the Association will submit to Mr. Goschen. The Fishmongers' Company have recently raised their contribution to the funds of the Association from £200 to £400 a year.

ON Monday evening various questions as to the effects of the dog-muzzling order were addressed to Mr. Chaplin in the House of Commons. He said:—"The return of deaths from hydrophobia since the muzzling order came into force are not at present in the hands of the Board of Agriculture. But I am glad to say, with regard to rabies, that in every county which has been placed under the regulations, and in the country as a whole, there has been a marked diminution in the number of outbreaks since the passing of the order. For instance, in 1889, for the last two quarters of that year there were 133 cases in the third, and 81 cases in the fourth quarter reported to the Board. For the first quarter of the present year they have been reduced to 39, and for the month of April there have only been seven cases throughout England, as compared with 11 for March, 14 for February, and 14 for January of the present year. In the metropolis and the West Riding, although there has been a large diminution, cases are still of constant occurrence, and there have also been comparatively recent outbreaks in Hampshire and West Sussex, in which latter county a muzzling order has been imposed by the local authority. With regard to Lancashire and the home counties of Essex, Hertfordshire, Surrey, and Kent, so far as they are not included in the metropolitan district, no cases have been reported for a considerable period, and if the reports continue to be as favourable in the case of the home counties as they have been of late, I shall hope to be able to modify the order, if it is not suspended, at no distant time. I may be allowed to add, as it will be of interest to the public, that since the order has been enforced, of the rabid dogs seized in public places, nine were properly and securely muzzled, and were thus prevented from doing mischief."

PROF. G. J. ROMANES, F.R.S., has been elected President of the Sunday Society, in succession to Sir James D. Linton, P.R.I., and will deliver his Presidential address at a meeting to be held in London in June.

THE Pharmaceutical Society will hold a *conversazione* at its house on Tuesday evening, May 20.

THE German Ornithological Society will hold its annual meeting at Berlin from May 9 to 12.

M. C. W. ROSSET has arrived at Hamburg after having been absent in Egypt, Cochin China, and China for three years. He has made a most interesting scientific collection, which will be presented to the Ethnographical Museum of Berlin.

THE recent investigations of Dr. Rudolf Kœnig, of Paris, into the composition of musical sounds and the theory of *timbre* will form the subject of an important paper to be read on May 16, at the meeting of the Physical Society, by Prof. Silvanus P. Thompson. Dr. Kœnig is sending over to this country for exhibition on this occasion a number of his wave-sirens and other expensive and elaborate apparatus, by which he has demonstrated the points of his research. Amongst the apparatus are some special appliances for producing audible beat-tones by the interference of two notes, each of which is too shrill to be separately heard. Musicians, as is well known, have never taken cordially to the current theories of Helmholtz respecting overtones and their relation to the consonance or dissonance of intervals and chords. As Dr. Kœnig's investigations have carried matters to a point beyond the speculations of Helmholtz, and not altogether in accordance with them, the occasion promises to be of unusual interest. It is expected that Dr. Kœnig will himself be present at the meeting, which is to be held at 6 o'clock at the Physical Laboratory of the Science Schools, South Kensington.

AT the Royal Academy banquet on Saturday, Sir William Thomson responded for "Science." He spoke chiefly of the mutual obligations of science and art. Aërial perspective, he said, first became known io scientific men through the artist's practical knowledge, and the use made of it in every conceivable representation of light and darkness, of house interiors and exteriors.

THE Select Committee on the sweating system refer in their Report to the evidence submitted to them as to the incompleteness of the education of workmen. "The remedies suggested," says the Committee, "are, on the one hand, a renewal of the apprenticeship system; and, on the other, the promotion of a larger system of technical education. We think that the encouragement of technical education for all classes of artisans is more likely to prove an efficient remedy than a recurrence to the old system of apprenticeship."

IT is reported from the ruby mines of Burmah that a ruby weighing 304 carats has been found.

A PUBLIC library is to be established at Hyderabad, and the Nizam's Government has also decided to undertake an archæological survey of the State.

FATHER FRANCIS DENZA, the Director of the new Vatican Observatory, is sending a circular in English to the Observatories of all English-speaking places, asking them to exchange publications with his institution. The authorities of the Vatican Observatory, which "now revives under the protection of His Holiness, Pope Leo XIII.," are anxious that it may render great service to science. Hence they feel the necessity of entering into communication with every existing scientific establishment of a similar kind. Father Denza expresses a hope that the directors to whom he appeals will let him have all the past publications of their respective Observatories.

MR. W. C. MILLS, Secretary of the Archæological Society of New Comerstown, Ohio, has found a Palæolithic flint implement in the gravel of the glacial terrace which everywhere lines the valley of the Tuscarawas river. Mr. G. F. Wright, to whom the implement was submitted, went to see the spot where it was discovered, and contributes to the *Nation* an interesting paper on his researches and conclusions. At this spot the surface of the terrace is thirty-five feet above the flood-plain of the Tuscarawas. The implement was found by Mr. Mills himself in undisturbed strata, fifteen feet below the surface of the terrace; so that it is "connected, beyond question, with the period when the terrace itself was in process of deposition." Thus it adds "another witness to the fact that man was in the

valley of the Mississippi while the ice of the glacial period still lingered over a large part of its northern area." This is only the fifth locality in which similar discoveries have been made in America—the other places being Trenton, N.J.; Madisonville, Ohio; Medora, Ind.; and Little Falls, Minn.

At a recent meeting of the Washington Chemical Society, Dr. Thomas Taylor, of the United States Department of Agriculture, exhibited a new flash-light intended to take the place of several kinds which have proved highly dangerous. The composition, as described by *Science*, consists largely of charcoal made from the silky down of the milk-weed—a form of carbon which Dr. Taylor prefers to all others, because of its freedom from ash. A few grains of this composition placed on tissue-paper, and lighted by a "punk-match," produced a prompt and blinding flash. The paper on which the powder rested was not even scorched. The flash being instantaneous, the heat is not sufficient to ignite the most inflammable material on which the powder may rest. An inferior flash-light being used, with the same paper for a base, the paper at once caught fire. This was owing to the comparatively slow combustion of the chemicals used in the inferior grade. Dr. Taylor said the powder of his new flash-light would not explode either by concussion or by friction.

At the meeting of the French Meteorological Society on April 1, the President read a circular from the Minister of Public Instruction, with reference to the Congress of Scientific Societies to be held at the Sorbonne from May 27 to 31. The following questions to be discussed are those more particularly of interest to meteorologists:—The study of the mistral; earthquakes; researches on the presence of aqueous vapour in the air by astronomical and spectroscopic observations; comparison of the climates of the different parts of France; the causes which seem to induce a general decrease in the waters of the north of Africa, and a change of climate; to fix for certain localities of the Alps and Pyrenees the present superior limit of vegetation, and to study the variations which it has experienced at different epochs; the study of the periodical phenomena of vegetation, dates of budding, flowering, and maturation; coincidence of these epochs with that of the appearance of the principal species of insects injurious to agriculture.

The Meteorological Council have just published the monthly and annual results of the meteorological observations taken at the stations of the Royal Engineers and the Army Medical Department, for the years 1852–86, comprising thirty-three stations, in different parts of the world. In the year 1852, meteorological instruments were supplied to the principal foreign stations of the Royal Engineers, and the observations were continued till March 1862, when the instruments were transferred to the Army Medical Department, as directions had been given by the War Office for similar observations to be taken by the medical officers in the Army, wherever stationed. The observations were partially published by the Board of Ordnance and the War Office, but as it was pointed out in the *Meteorologische Zeitschrift* for March 1886, that it was "most desirable that this valuable store of observations, especially from stations for which hardly any other information for the period exists, should be worked up according to the modern requirements of the science, and then published," the Meteorological Council decided to undertake the work, and a large mass of original observations was handed over to that body. The result is the present volume of 261 + xiii. large quarto pages of carefully revised results for separate months and years. The combined results, for as many years as possible for each station, accompanied by a brief discussion of this valuable material, would no doubt be welcomed by meteorologists.

Dr. Dixon, Professor of Hygiene at the University of Pennsylvania, has been studying air and dust obtained in street cars. *Science* says he has found in them "the germs of many diseases, contagious and otherwise. Better ventilation and more effective cleansing are sorely needed."

In the current number of the *Zoologist*, Mr. E. L. Mitford writes of the survival of the beaver in Western Europe. Some fifteen years ago he saw in the museum at Bayonne a very large white beaver, which had been killed in the Rhone. He was told that it was the last of its race found in Europe. But this year, being at Hyères, where there is a museum with a very fine collection of indigenous birds and quadrupeds, he found another fine specimen, colour light brown, measuring three feet from snout to end of tail. This was obtained about four or five years ago, and is one of several that were sent to M. Fiépi, a naturalist and taxidermist of Marseilles. They were taken in the Rhone at St. Meree, in the neighbourhood of Arles. M. Catal, the naturalist of the Hyères Museum, talking of the subject with Mr. Mitford, said that beavers were more numerous formerly on the Rhone; that the great floods of 1846 had destroyed a large number, and made them more easily captured; and that subsequent inundations had made them much rarer. They are still to be found on the Rhone and its affluents, the Gardon, the Durance, and the Isère below Valence, also lower down the Rhone at Arles, Beaucaire, and Taralcon. They seem to have abandoned their custom of building huts and dams; the race no longer being sufficiently numerous to live in communities, they now live in deep burrows. In 1827 a number of the huts of the beaver were found on the Elbe at its meeting with the Nuthe, near Magdeburg.

The Director of the Norwegian Geological Survey, Dr. Hans Reusch, has lately published a small geological map of the Scandinavian peninsula, Finland, and Denmark. It includes also representations of Greenland, Iceland, Spitzbergen, and the Faroe Islands. The Norwegian terms used in the explanation of the colours are translated into English. The publishers are H. Aschehoug and Co., Christiania.

A work entitled "Dogs, Jackals, Wolves, and Foxes: a Monograph of the Canidæ," is being prepared by Mr. St. George Mivart, F.R.S. It will contain a description, with a plate drawn and coloured from nature, and often from life, of every species which the author thinks can fairly claim to be regarded as distinct, and also of various marked varieties of what he regards as probably one species. In addition to an account of the habits, geographical distribution, and life-history of each species, there will be given in an introduction, enriched with woodcuts, what the author deems a sufficient description of the anatomy of the group, of the structural relations of the Canidæ to other animals, their position in zoological classification, and the general relations they bear to the past and present history of this planet. The execution of the plates has been entrusted to Mr. J. G. Keulemans.

A new and most useful edition of the "Guide" to the exhibition galleries of the Department of Geology and Palæontology in the Natural History Museum, Cromwell Road, has been issued. In the preface, Dr. Henry Woodward explains that the publication of Mr. R. Lydekker's Museum Catalogues of the "Fossil Mammalia," parts i.–v. (1885–87), and the "Reptilia and Amphibia," parts i.–iv. (1888–89), has compelled the rearrangement of a great part of these collections, and changed the plan of the "Guide." Much additional information is given in the present edition, and the illustrations have been increased from 49 to 211. It has therefore been found necessary to subdivide the work into two parts. The first part deals with fossil mammals and birds, the second with fossil reptiles, fishes, and invertebrates.

Messrs. Neill and Co. have issued a volume giving a list of the contents of the first thirty-four volumes of the Transactions of the Royal Society of Edinburgh, with an index of authors and an index of subjects. The Society was founded in 1783, and published the first volume of its Transactions in 1789, adopting demy quarto as the size of the page. A slightly larger size has now been chosen, that the Society's Transactions may be uniform with those of the Royal Society. A new series may thus be said to have been begun. Messrs. Neill and Co., who have been printers to the Society since its foundation, present a copy of the volume to each member, "as a slight acknowledgment of their appreciation of the favour shown their firm for more than a century."

We have received the twentieth annual report of the Wellington College Natural Science Society. A good record of work in various departments is presented, and an account of some very interesting lectures is given in the "minutes of open meetings."

Some time ago the Japanese Minister of Education summoned a committee to discuss the system of building best adapted to withstand earthquakes. For the use of this committee, Prof. Milne, of Tokio, compiled a great quantity of information respecting building in earthquake countries. The various reports collected by him, with some original articles of his own, he has now brought together in a work which is printed as vol. xiv. of the Transactions of the Seismological Society of Japan. The compilation ought to be of great service to builders in countries where shocks of earthquake are frequently felt.

Messrs. Williams and Norgate have published a second edition of Mr. F. Howard Collins's "Epitome of the Synthetic Philosophy," which we recently reviewed. The work has been favourably received in America, and is being translated into French, German, and Russian.

A volume on the Paris Exhibition of 1889, by M. Henri de Parville, has just been published by M. J. Rothschild. It is pleasantly written, and illustrated by 700 vignettes.

The Geneva Society of Physics and Natural History has issued the second part of the thirtieth volume of its *Mémoires*. Besides the President's Report for 1888, a bibliographical bulletin, and a list of members, the volume contains papers on the movements of electrified bodies, by M. Ch. Cellérier; new or little-known locustides in the Museum of Geneva, by M. Alph. Pictet; on the flora of Paraguay, by MM. M. Micheli and R. Chadat; and on certain fossils of Japan, by MM. J. Brun and J. Tempère. The volume includes many illustrations.

Messrs. Macmillan and Bowes, Cambridge, have issued the first part of a Catalogue (No. 230) of books on the mathematics, pure and applied, containing many works of the old mathematicians, mathematical and astronomical journals, observations, &c., including many from the libraries of the late Arthur Buchheim, Fellow of New College, Oxford, and E. Temperley, Fellow of Queens' College, Cambridge.

A Catalogue of zoological and palæontological works has been issued by Messrs. Dulau and Co. It includes works on mammalia, and on anthropology and ethnography.

Prof. Everett sends us the following extract from the *East Anglian Daily Times*. It is by Mr. Herman Bidell, of Playford, who is well known in Suffolk, and is thoroughly competent to describe accurately phenomena he observes:—"I shall be glad to draw the attention of those interested in thunderstorms to a magnificent example of ruin by lightning we have in this village. The parish of Playford was visited on Saturday last (the 26th) by one of those volatile clouds heavily charged with electricity that so often remind us of the approach of summer. The tree struck stands about 300 yards north-east of the church, close by the footpath leading to Great Bealings, one of a row of 'old English' poplars running east and west. At the foot the tree is about 2½ feet in diameter, tapering more or less regularly to a 10-inch diameter at the top. Here the electric fluid came in contact with the trunk some 40 feet from the ground. The two topmost branches are intact, but the bark is completely stripped from top to bottom, the southern half of the body being riven into matchwood. The storm came up from north-west, with a very light breeze, shifting right and left of north. The cloud was a dense dark blue—the effect, in part, of the sun in front—a detached mass of vapour with fringed edges, differing little, except in density and its proximity to the earth, from others which during the forenoon had floated over. At half-past one o'clock a few drops warned four or five men at work close to the tree to take shelter under a stack 200 yards off—a fortunate warning, for no sooner had the cloud drifted overhead than a blinding flash, accompanied by a terrific peal of thunder, left the tree a magnificent ruin, spread over not less than two acres of land, more or less covered with bark, branches, and riven trunk. One solid piece of 5½ pounds was picked up 126 yards away from the tree. Other *débris* lies 70 yards in an opposite direction, and as an evidence of still more inconceivable force, small pieces of riven trunk or bark, some under half an ounce in weight, were found right in the face of the wind, nearly 60 yards from the tree. What force could have been applied to such light particles is beyond comprehension. Nothing that I have ever seen effected by lightning approaches this ruin. Larger trees have been shivered in this parish, but I never saw a tree completely barked all round, with one half literally riven into fibre, leaving the other half of the trunk a whitened stem, still standing as a forty-feet shaft to be seen a mile away. (The remnant is a conspicuous object in a north-westerly direction all the way from a point east of the old Kesgrave Schools for half a mile towards Ipswich on the Martlesham and Rushmere roads). The electric fluid left the tree at the foot, following the direction of the fence for about 15 or 20 feet, threw up a sod about a foot square, and there pierced the soil into the earth. Four hundred yards in a direct line north-east of the tree stands Playford Mount, the residence of Mr. Kemp-West, a commanding object in the landscape. Here some half-dozen of the fine glass plates in the front windows are shattered to atoms, the result, I apprehend, of concussion from the report of the explosion. I have never known this effect from the severest storm in the neighbourhood, but the thunderclap is described as terrific. The tree, as standing, is worth going to see, and, I will add, is of easy access from the road past the church."

The *Engineer* and *Engineering* for May 2 contain much information concerning the proposed great tower in London. The drawings, plans, and designs of the competing schemes are now being exhibited in the Drapers' Hall, Throgmorton Street, E.C. *Engineering* appears to think that, if the tower is to pay, it must be provided with some attractions to bring the people again and again; and if these attractions could be raised 200 feet or 500 feet above the smoke, they would be immensely increased. The country cousin and the conscientious sight-seer would go to the summit, but the first stage would detain the bulk of the visitors. *Engineering* also observes that, in reviewing the various designs, we must frankly admit that none excels the Eiffel Tower in beauty and grace. No fewer than eighty-six competitors have sent in designs.

An interesting paper upon cyanogen iodide, CNI, is communicated to the current number of the *Berichte* by Drs. Seubert and Pollard, of the University of Tübingen. On account, probably, of the extremely poisonous nature of this compound,

rendered even more dangerous by reason of its great volatility, little has hitherto been done towards completing its chemical history beyond a mere description of its more evident properties. Determinations either of its density or its melting-point appear never to have been attempted, and it was with the object of supplying these deficiencies that the work in the Tübingen Laboratory was undertaken. Everyone who has ever prepared this exceptionally beautiful substance for lecture or other purposes will remember the exquisite manner in which it sublimes, forming long, delicate, colourless, but very highly refractive needles, bridging over from side to side of the wide tube or flask in which the operation is performed. Often these elongated prisms attain the length of half a dozen inches or more, and frequently form an interlacing network among which may be seen perched here and there star-shaped or flower-like aggregates of the smaller crystals. Perhaps the most remarkable property of these crystals is to be found in the manner in which they re-sublime from one side of the vessel to the other according as their position is varied as regards the direction of the light which falls upon them. Drs. Seubert and Pollard prepared their specimens by the old method first used by Sir Humphrey Davy, the action of iodine upon mercuric cyanide, $Hg(CN)_2 + 2I_2 = HgI_2 + 2CNI$. About 10 grams of the finely-powdered and well-dried mixture of iodine and cyanide of quicksilver, in the proportion of one molecule of each so as to avoid the presence of much free iodine in the sublimate, was placed in a wide test-tube and interpersed with glass beads in order to render the mixture as porous as possible. The test-tube was then placed at the bottom of a wider glass tube closed at the lower end, and fitted at the upper with a calcium chloride drying tube to prevent access of moisture. The apparatus was then allowed to stand for about three days in a position where it could receive direct sunlight; at the end of this time the reaction was almost complete, the mixture being brilliant red from formation of mercuric iodide. The lower end of the tube was then placed in a hot water bath, when the iodide of cyanogen sublimed in the manner above described into the upper cooler part of the tube. In order to determine the melting point, small quantities were placed in capillary tubes and hermetically sealed, for if the upper end were left open, as is usually the case in taking a melting-point, the cyanide would simply volatilize without fusion. The melting-point was in this way found to be 146°·5 C., and the solidifying point 143°. The vapour-density was determined by Victor Meyer's method, and found to be 5·28, corresponding to the simple formula, CNI. The lowest temperature at which the substance becomes completely and rapidly converted to the gaseous condition appears to be about 250°. The iodide is therefore analogous to the simple bromide and chloride of cyanogen, CNBr and CNCl, and not to the triple polymers tri-cyanogen bromide and chloride, $C_3N_3Br_3$ and $C_3N_3Cl_3$.

The additions to the Zoological Society's Gardens during the past week include the Wild Boars (*Sus scrofa* jv.) bred in Scotland, presented by the Lord Hebrand Russell; a Ring-tailed Coati (*Nasua rufa* ♂) from the Argentine Republic, presented by Mr. R. E. Moore; a Louisianian Meadow Starling (*Sturnella ludoviciana* ♀) from North America, a Black-bellied Sand Grouse (*Pterocles arenarius* ♀) from India, presented by Mr. W. H. St. Quintin; four variegated Sheldrakes (*Tadorna variegata* ♂ ♂ ♂ ♂) from New Zealand, presented by Captain C. A. Findlay, R.N.R.; a Rhomb-marked Snake (*Psammophylax rhombeatus*) from South Africa, presented by Miss Harris; three Common Vipers (*Vipera berus*) from Sussex, presented by Dr. C. W. Cousens; a Green Lizard (*Lacerta viridis*), a Three-toed Skink (*Seps tridactylus*) from France, presented Mr. J. C. Warbury; a Sooty Phalanger (*Phalangista fuliginosa* ♂) from Australia, deposited; a Black-headed Lemur (*Lemur brunneus*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

Objects for the Spectroscope.

Sidereal Time at Greenwich at 10 p.m. on May 8 13h. 6m. 42s.

Name.	Mag.	Colour.	R.A. 1890.	Decl. 1890.

(6) V Virginis	Var.	Yellow-red.	13 22 7	− 2 36

Remarks.

(1) The spectrum of this bright nebula does not appear to have been yet recorded. Smyth describes it as "a conspicuous nebula, magnificent in size and brightness." In the General Catalogue it is described as "a very remarkable object; very bright; very large; very much extended in the direction 120°; brightens in the middle to a small bright nucleus, which is possibly a double star." The nebula is in the constellation Coma Berenices, and is now very favourably situated for observations.

(2) This is the famous spiral nebula in Canes Venatici. The details of the nebula are so well-known that a full description is not necessary here. In all but the largest telescopes it simply appears as a double nebula with the two nebulosities running into each other, one of them being surrounded by a ring which is variable in brightness. Smyth likens this to a "ghost" of Saturn. According to Huggins the spectrum is continuous, but some parts were thought to be abnormally bright. Although the observations will not be easy, it is very important that the positions of such bright parts should be measured, if only approximately. In such cases as this it is probable that we shall find spectroscopic connecting links between the bright-line nebulæ and stars which are well advanced in condensation. Our knowledge of the relations between nebulæ and comets is also likely to be advanced in this way.

(3) This is a very fine star of Group II. The bands are very wide and dark, even in the ultra-blue, but especially in the red (Dunér). The star belongs to a late stage of the group, and may be usefully re-examined for further details.

(4) A star of the solar type (Vogel). The usual differential observations as to whether the star is increasing in temperature (Group III.), or decreasing (Group V.) are required. The spectra of this class of stars should be very carefully examined for remnants of the strong bands in the red, which characterize the later stages of Group II., and which are also seen in Aldebaran. If these are found, the star is obviously at an early stage of Group III. It has also become very important to determine whether there are any stars intermediate between stars like the sun and stars of Group VI., and in these more detailed observations this should be borne in mind. The carbon band near *b* will probably be the first to appear, and the presence or absence of traces of this band should be always noted. It is most likely to occur in stars of an orange or reddish tint.

(5) Spica has a spectrum of Group IV. The only observations likely to be of service are those comparing the thicknesses of such lines as *b*, E, and D with their thickness in other bright stars of the same group (*e.g.* α Lyræ). This will determine its relative temperature.

(6) This variable will reach a maximum about May 9. It ranges in magnitude from 8–9 at maximum, to < 13 at minimum in a period of about 251 days. The spectrum is still doubtful; Gore writes it III. ?

A. Fowler.

Structure of the Corona.—The Smithsonian Institution has had two plates prepared, containing nine photographs of the total eclipse of the sun of January 1, 1889, and distributed them amongst astronomers and others interested in solar physics. All the photographs have been reduced to a uniform diameter, and at Prof. Langley's request, Prof. Todd has contributed a descriptive note to accompany them. In the remarks on the structure of the corona it is noted:—

(1) The axis of symmetry of the corona does not coincide with the axis of revolution of the sun as determined from the solar

spots. The corona appears to be at least a triple phenomenon made up of—

(*a*) The polar rays, seen most prominently about the poles.

(*b*) The inner equatorial corona, the lower regions of which bear some resemblance to an outer solar atmosphere.

(*c*) The outer equatorial corona, consisting of the long streamers for the most part only visible to the naked eye.

(2) The polar corona consists of rays, straight or nearly so, and radial from neither the sun's centre nor the sun's poles. Rather they seem to radiate from areas the centres of which are adjacent to the sun's poles.

(3) The inner equatorial corona emits a large percentage of the total light of the corona; the streamers, however, are not generally so sharply defined as about the poles, and many of them appear to have a real curvature. Four large prominences are visible at about 35° of solar latitude, as if to suggest some connection between the protuberances and the corona.

(4) The equatorial streamers of the corona are very slightly curved, being convergent on the east side of the sun, and divergent on the west.

The fact of chief importance established appears to be the periodicity of the outer corona in a cycle probably of equal duration with that of the solar spots. The epoch of greatest extension of the equatorial corona appears to coincide very nearly with the epoch of minimum sun-spots.

Prof. Todd also directs attention to the most important points requiring elucidation, and throws out a few suggestions for future eclipse observations.

Brooks's Comet (*a* 1890).—The following ephemeris has been computed by Dr. Bidschof (*Astr. Nach.*, No. 2966), and is in continuation of that previously given (Nature, vol. xli. p. 571):—

Ephemeris for Berlin Midnight.

1890.	R.A. h. m. s.	Decl. ° ′	Log *r*.	Log Δ	Brightness.
May 6	20 53 21	+34 9·6	0·2874	0·2596	2·60
10	46 41	37 44·1	0·2857	0·2449	2·80
14	38 9	41 28·5	0·2843	0·2314	3·00
18	27 13	45 20·2	0·2832	0·2195	3·18
22	13 16	49 14·9	0·2824	0·2096	3·34
26	19 55 28	53 6·2	0·2818	0·2022	3·47
30	32 54	56 46·1	0·2815	0·1976	3·55

The brightness at discovery (March 21) has been taken as unity.

Discovery of Minor Planets.—Two more asteroids were discovered by Herr Palisa, at Vienna, on April 25, and observed independently by M. Charlois, at Nice, on the following night. The magnitudes of the planets are 13 and 12 respectively, and their numbers are (291) and (292). Prof. Krueger thinks that the latter is probably Scylla (*Astr. Nach.*, 2966).

THE INSTITUTION OF MECHANICAL ENGINEERS.

An ordinary general meeting of the Institution of Mechanical Engineers was held on the Thursday and Friday of last week; the President, Mr. J. Tomlinson, in the chair.

The second meeting of the year is not generally looked on as of great importance, but it is a long time since we remember one of such meagre proportions in one respect as that with which we are now dealing, for there was only one paper on the agenda; that and the President's address constituted the whole programme. What the proceedings lacked in variety and amplitude was, however, fully compensated for in solid value. The one paper, Prof. Kennedy's, is full of valuable information, and Mr. Tomlinson's address came as a most welcome surprise to a good many. In the first place it was short, and, secondly, it was practical—two virtues which appeal strongly to engineers when there is talking to be done; but beyond that it was one of the most interesting Presidential addresses we have heard for many a day at any of the Engineering Societies. The reason for this is not far to seek. Mr. Tomlinson simply narrated his own experience in plain language, eschewing those ornamental tags of rhetoric which many people look on as essential when they have to speak in public; and as his experience extends back to a very interesting period of railway engineering, the address proved an exceptionally happy effort.

Mr. Tomlinson has been, as he said, a railway man all his life; and, indeed, he has been connected with the engineering departments of more than half a dozen railways, from the Stockton and Darlington up to the Metropolitan. His father was passenger superintendent to the former line. His recollection therefore carries him back to the very early days of the locomotive. His first knowledge extends to the year 1837, when he was employed at the works of Timothy Hackworth, of Shildon. Perhaps no better instance could be given of the simplicity of those Arcadian days than the fact that Hackworth was at once locomotive superintendent and contractor to the railway. Such a dual position might cause invidious remarks on the part of shareholders in the present day. Mr. Tomlinson remembered the three original locomotives placed on the Stockton and Darlington line. One of them, the *Locomotive*, now stands on a pedestal in front of the North Road Station at Darlington. The load for this engine was about 22 tons of empty waggons to draw up hill; whilst down the hill to Middlesborough the waggons loaded, weighing 64 tons, were drawn. The weight of the engine and two tenders loaded was about 15 tons. Unfortunately there was no record kept of the consumption of fuel, but Mr. Tomlinson used to help put the coal on the tender, and he estimates the quantity to have been 16 to 17 cwts. for 48 miles, or about 40 lbs. per engine mile; but it must be remembered that the gradient was all in favour of the load—in fact, the greater part of the fuel was consumed on the return journey of empty trucks. The cylinders were 10 inches in diameter by 24 inches stroke. The eccentrics had to be changed for back and forward gear by hand, the boiler pressures were 30 to 35 lbs. per square inch, and the pistons were packed with a spun-yarn gasket. As the cylinders were vertical there were necessarily no engine springs. There were no brakes, no water-gauge glass, no head or tail lamps, and no whistle. We have not space to follow Mr. Tomlinson in his interesting engineering reminiscences. Perhaps, since Mr. T. R. Crampton has gone, there is only one other engineer living who could give us such unique personal experience of early locomotive days. If so, that engineer is Mr. E. Woods, Past-President of the Institution of Civil Engineers.

Prof. Alexander Kennedy's paper constituted the second report of the Research Committee appointed by the Council of the Institution to investigate the Marine Engineering question. Within the last few years the Institution has made quite a special feature of these research committees, and we know of no better way in which it could carry out the object of its existence, and, at the same time, keep down the ever-growing financial surplus. The Research Committee on Friction and the Research Committee on Rivetting would have been of great service to engineers if only from the fact that they collected and put in concise form the knowledge already existing on the subjects; but they did more than this, for they made experiments of their own by which doubtful points were cleared up and new possibilities were suggested. The Marine Engine Committee are following the same useful course under the guidance of their Chairman, Prof. Kennedy, who, it may be remarked, gained his first experience as an engineer in the once celebrated Thames-side marine engineering establishment of the Dudgeons.

As we have said, this is the second report of the Committee, the first, which was read last year, being on the trials of the s.s. *Meteor*, a London and Edinburgh steamer of 692 registered tons. The vessels since then under trial, and dealt with in the second report, are the *Fusi Yama*, the *Colchester*, and the *Tartar*. The first is an ordinary trading vessel of 214·3 feet long b.p., 29·3 feet beam, 20·5 feet deep, and of 2175 tons displacement at trial draught. The trial run was from Gravesend to Portland. The engines are by Samuelson, of Hull, and had just been overhauled. They are of the ordinary two-cylinder compound type. The *Colchester* is the latest built vessel of the Great Eastern Railway on the Antwerp service. She is 281 feet long, 31 feet beam, and 15·2 deep. Her trial displacement was 1675 tons. She is a twin-screw ship, the engines being ordinary two-cylinder compounds. The trial run was from the Humber to Harwich, the engines having been overhauled in the former river. The *Tartar* was selected as an excellent example of modern economical engines in a cargo-carrying steamer—what is generally known as an "ocean tramp." She is 332 feet long, 38 feet wide, and 27 feet deep. Her displacement tonnage on trial was 2250 tons. She has triple compound engines of the three-crank type. The trial run was from the Thames to Portland. The vessel was light, so that the engines were working at very low power, and, in addition to this, bad weather was met

with on the voyage, so that the recording of results was much interfered with. It will be noticed that the figures bearing on the efficiency of the *Tartar's* boilers are not given in the table. The reason is that the coefficient based on the recorded data comes out so high that the boilers could hardly have been evaporating all the feed water pumped into them. In ordinary cases we should naturally attribute this to priming; but the power developed was so small that we hesitate to apply this solution in the present case. On the other hand, the phenomenon of excessive cylinder condensation would be induced by working a big engine at low power. We have not, however, sufficient data to enable anything positive to be advanced in this connection. We understand that in ordinary working the boilers show no sign of excessive priming, and the steam space is said to be ample. The *Meteor*, the first vessel experimented upon, is 261 feet long, 32·1 feet wide, and 19·3 feet deep. Her trial displacement was 2090 tons. The engines are of the triple compound type, with three cranks at equal angles.

It will be evident that we have not space to give details of the trials as set forth by Prof. Kennedy, and any fairly intelligible abstract is difficult to make. The paper itself is merely a record of facts—a most admirably arranged record we may say in passing—and each fact is so interdependent on others, that it is difficult to make a selection. We will, however, briefly state in the form of a table a few of the leading features and final results, referring those of our readers most interested in the subject to the report itself. We include the *Meteor*, as her record is necessary to make the matter complete.

	Name of vessel.			
	Meteor.	*Fusi Yama.*	*Colchester.*	*Tartar.*
Boiler pressure above atmosphere in pounds per square inch	145·2	56·84	80·5	143·6
Vacuum in condenser below atmosphere in pounds per square inch	12·17	12·48	12·49	12·9
Revolutions per minute	71·78	55·59	{86·0 / 87·1}	70·0
Total mean indicated horse-power	199·4	371·3	{1022·5 / 957·2}	1087·4

,, ,, ,, ,, unaccounted for	11·3	8·4	8·3	—
Efficiency of boiler per cent.	62·0	67·2	62	—
,, ,, engine	16·1	11·2	10·7	11·5
,, ,, ,, and boiler combined	10·0	7·6	6·6	9·7

A discussion followed the reading of the paper, the most interesting feature of which was a description, by Mr. Willans, of a device he had used for investigating the effect of condensed steam in an engine cylinder. For this and other points in connection with the trials we must refer our readers to the Transactions of the Institution.

THE SCIENTIFIC INVESTIGATIONS OF THE FISHERY BOARD FOR SCOTLAND.[1]

WHATEVER may be wanting to Scotchmen in the way of Home Rule, they have no cause to complain of a want of Home Rule in their fisheries. The Fishery Board for Scotland is a complete and independent body, exercising complete jurisdiction over all the Scottish coasts, provided with an ample staff, and in receipt of a considerable amount of Government money. We learn from the introduction to the present Report that the scientific staff consists of three trained naturalists and an assistant naturalist, and besides these there is a Committee of eminent scientific men, including representatives from all the Scottish Universities. Finally, the Board has a steamer, the *Garland*, specially devoted to scientific investigations, and is able to make use of the fishery cruisers for the same purpose.

Under these favourable circumstances, and especially in virtue of the powers granted by the Sea Fisheries (Scotland) Amendment Act, 1885, the Scotch Fishery Board has exceptional opportunities for making extensive and continuous scientific investigations. The investigations for 1888 are embodied in the Report which is here dealt with. The Report is divided into three Sections. Section A is largely devoted to the experimental trawling of the *Garland* in the areas closed against beam-trawling, and to a number of statistical tables drawn up for the purpose of comparison with those experiments. This experimental trawling requires some explanation. The Act above-mentioned empowers the Scotch Fishery Board, under stated circumstances, to make by-laws for restricting or prohibiting, either entirely or partially, any method of fishing for sea fish within any specified area in any part of the sea adjoining Scotland, and within the exclusive fishery limits of the British Islands.

In accordance with the Act, by-laws were framed, prohibiting beam-trawling in districts which may roughly be described as the Firth of Forth, St. Andrew's Bay, and the Firth of Tay, and part of the sea off the coast of Aberdeenshire and Kincardineshire. This by-law came into force on April 5, 1886. Since that date the *Garland* has trawled periodically over certain definite stations within the prohibited areas, and the catches have been carefully tabulated, both as regards size and quantity. The object of the experiment is, of course, to study the effect of an enforced period of rest on the piscine fauna of the inclosed and adjacent areas, and to obtain information under the following heads:—(1) Whether the cessation of beam-trawling would cause any marked increase in (*a*) the number, (*b*) the size of trawl-fish within the closed areas. (2) Whether the closure would affect the catches of line-fishermen working in those areas. (3) Whether the closure would affect the catches of trawlers and other fishermen in adjacent areas. No fault can be found with the method of investigation, which is the only possible one under the circumstances; but, as might be expected, the results are influenced by a number of secondary causes which obscure the effect of prohibiting beam-trawling in the places mentioned. This may easily be seen by reference to the published accounts of the experiments. It was found in 1887, a year after the closure, that the average take of fish per "shot" was much greater than in the previous year in the closed

[1] "Seventh Annual Report of the Fishery Board for Scotland, being for the Year 1888." Part III., Scientific Investigations. Presented to both Houses of Parliament in pursuance of Act 45 and 46 Vict., cap. 78. (Edinburgh, 1889.)

areas, and that the increase was chiefly in flat fish, though also in round fish. At the same time, there was an increase in the take of all classes of fish in the free waters outside, but in general the increase in this case was in round fish, rather than in flat fish. So far, then, the experiment promised to show an immediate and most beneficial result. In 1888, however, the take of fish was very much diminished. The average number of fish of all kinds captured in the Firth of Forth per "shot" amounted to 211. In 1887 the corresponding average was 351, and in 1886, 251. There was also a considerable reduction in the average take in offshore waters, but the reduction was less than that in the closed area. Moreover, the proportional decrease of flat fish was greater than that of round fish in the closed waters, and this was more marked in the offshore waters. In St. Andrew's Bay there was, similarly, a great diminution of all kinds of fish, especially of flat fish; but outside, in the free sea, there was an increase in the flat fish and a great decrease of round fish. These negative and partly contradictory results were, without doubt, due to the exceptionally stormy weather in 1888. It shows, however, the great difficulty and complication attending fishery investigations. Nothing could seem to be more obvious than that, if trawling were prohibited in a certain area, less fish would be caught, and that their numbers would increase. The first results of the trawling experiments go to show that this is by no means necessarily the case, but that there are causes more powerful than beam-trawling which affect the numbers of fish in any season.

There are also statistics showing the relative amounts of fish caught by line in restricted and unrestricted areas—that is to say, areas where beam-trawling is prohibited and where it is permitted. These statistics show an increase in the weight of fish caught by line has taken place in 1888, in both areas, but that it is proportionally larger in the unrestricted than in the restricted areas. The increase is not due to a larger number of boats and men engaged in fishing, for these have actually decreased. The statistics of line-fishing are certainly curiously contradictory to those of beam-trawling, for whereas, in 1888, the latter mode of fishing showed a decrease of flat fish in closed areas, the line-fishing showed an increase of flat fish.

It is really impossible to draw any conclusions from statistics extending over so few years. After ten years of work we shall be in a better position to judge the result of the experiment of closing certain inshore waters against trawlers. So far, it must be confessed that no case whatever has been made out against them, and the line fishermen seem to be quite as efficient in depopulating a district. From the way in which the summaries of the statistics are written, the Fishery Board may be suspected of an unconscious leaning towards the interests of the line-fishermen.

No fewer than 129 pages are devoted to the statistical tables referred to.

A very interesting Report is given in Section B (biological investigations) by Prof. Ewart on the spawning of British marine food-fishes. Space forbids a detailed criticism of this Report, but it is definite and satisfactory, and shows that, contrary to the common belief, the majority of British food-fishes do not come inshore to spawn, but at the spawning season they congregate in shoals in deeper waters. This Report is followed by a paper on the food of fishes, by Mr. Ramsay Smith. The greater part of the observations and records necessary for this work were carried out by Mr. Thomas Scott, who is a veritable giant in practical work at sea. The paper on the pelagic fauna of the Bay of St. Andrew's, by Prof. McIntosh, may be considered as complementary to Mr. Ramsay Smith's paper, since the pelagic organisms are considered from the point of view of food for adult and larval fish. Prof. McIntosh's paper, giving a record of all the pelagic organisms observed throughout the year, is a thorough and important contribution to our knowledge of the subject, and has a high practical value, especially that part of it relating to fish ova and larvæ. At the same time, it may be questioned whether the subject of fish food is not dragged in a little too much. Is it perfectly ingenuous to give a series of beautifully-coloured drawings of the metamorphoses of Actinotrocha, and to label them "Pelagic fish food"?

The descriptions of, and suggestions about, the mussel and clam beds are of obvious practical interest, and Dr. Edington's paper on the Saprolegnia of the salmon disease gives promise of a wide extension of our knowledge of a difficult subject.

The Report concludes with a careful record of physical observations made in the North Sea. The value of the physical work of the Board would be much enhanced if arrangements could be made for taking daily observations at definite stations around the Scotch coast. Such observing stations have been established by the United States Fish Commission and by the German Commission for the Scientific Investigation of German Seas, and have been fruitful of results.

The Fishery Board, it may be noticed, is only engaged in one *experiment*—that of closing certain areas against beam-trawling. The remainder of the work is in the preliminary stage of *inquiry*. In the earlier stages of fishery investigation, a large amount of biological and physical inquiry into the natural conditions of the sea is absolutely necessary, as a guide for future experiments upon marine organisms. To those who do not consider the matter attentively, these investigations may seem useless and superfluous, but they are not. It must be observed, however, that these inquiries are not an end in themselves, as in philosophical biology, but must be undertaken solely with the view of applying the experience gained to future attempts to solve the fishery problem. For example, an inquiry into the food of the different species of fishes of a district need only be made once; it is sufficient for practical purposes to know what they do generally eat, without inquiring what they may eat in exceptional circumstances. An inquiry into the relations of pelagic organisms is most useful as a guide to the life-conditions and food of fish larva and certain adult fish, but a great deal of strictly scientific work on this subject is useless; the morphology and phylogeny of each pelagic organism has not the slightest bearing on fishery questions.

The statement of the fishery question is perfectly simple. Given a continuous decrease in a number of valuable fish, due to over-fishing, how may the diminution be checked, and a continuous future supply be insured? The answer to the question is very difficult. Life in the sea is beyond control, and, to a large extent, beyond observation, for the trawl and dredge give a very insufficient idea of the conditions of marine life. There is not so close an analogy between agriculture and fisheries, as is sometimes implied in language. The sea cannot be parcelled out into inclosures; it cannot be cultivated with different kinds of crops at will; its fishes cannot be kept in confinement and protected from their enemies and the weather, nor can they be fed at regular periods as live stock are. It is misleading to talk of "reaping a harvest that is never sown," when the power of sowing *and caring for the crop* is out of reach. The ultimate aim of all scientific investigations in fishery matters must be to find out what circumstances are in human power to control, and to show how that control may best be exercised.

The first and obvious subjects for control are the fishermen themselves. If they are the cause of the depopulation of the seas, such a check may be put upon their proceedings as to obviate the evil. This may be done in one of two ways: by prohibiting fishing altogether in certain specified areas, as has been partially done by the Scotch Fishery Board, so as to afford centres from which fish may spread into the surrounding seas, or by the establishment of close seasons for different species of fish. Both methods are attended with great difficulties, which have been discussed over and over again. They may be summed up as hardship to the fishermen, and the impossibility of preventing the destruction of one species of fish whilst another is being fished for. To establish a close season which would prevent any breeding-fish being caught, would be to prohibit all fishing for three parts of the year. Secondly, the ova of breeding-fish may be artificially fertilized, the fry hatched out and turned out in great numbers to restock the waters that have been depopulated. This method is said to have been attended with success, and demands a further trial; but it must not be supposed that this process in any way resembles the rearing of domestic animals on land, or even the culture of fresh-water fish. The fry, once turned out, are lost sight of, are exposed to the attacks of numerous enemies, and are beyond all further human care. Thirdly, fish might be protected by the wholesale destruction of their natural enemies other than man, just as game is protected by the destruction of stoats, carrion-crows, and other vermin. No doubt a general massacre of cormorants, gannets, and dog-fish would make a great difference to the annual destruction of fish on our coasts, but in the case of the birds, such a course would meet with great opposition; and in the case of dog-fishes, extermination, or even an appreciable reduction in number, would be nearly impossible. Lastly, attempts may be made at culture *sensu stricto*. Young fish may be caught by the ordinary methods, and kept in suitably constructed fattening-ponds until

they are of saleable size; or, to carry the process a step further, the larvæ reared in hatcheries may be turned into similar ponds and brought to maturity. These operations have been conducted with success in more places than one, but the only places where marine fish-culture forms an industry of any importance is in the Adriatic, where there are large inclosures known as *valli*, in which young fry, caught in the open sea, are inclosed and brought to a marketable condition. The possibility of cultivating mussels and oysters in the like manner is too well known to require further mention, and it is quite possible that it may be found practicable to apply the system of culture to lobsters.

These are the practical questions to which fishery officers will have to turn their attention. That a preliminary scientific training is necessary is obvious, for the art of culture requires the most exact knowledge possible of the animals under cultivation, and success will in each case depend on the extent to which the necessities of the organism are studied and supplied. But abstract scientific study must give way to practice; as soon as a man allows the problems of morphology and phylogeny to distract his attention, he will become less careful of his practical experiments, and they will end in disappointment. The Scotch Fishery Board has made an excellent beginning in its trawling experiments; in a short time it may be hoped that its staff will be engaged in numerous other experiments on the protection and production of fishes, crustacea, and mollusks, to which many of the observations published in the Seventh Report are but the preliminary. G. C. B.

THE FIXATION OF FREE NITROGEN.[1]

In a paper communicated to the Royal Society in 1887-88 (Phil. Trans., 1889), the authors discussed the history and present position of the question of the sources of the nitrogen of vegetation. The earlier results obtained at Rothamsted, as well as those of Boussingault, under conditions in which the action both of electricity and of microbes was excluded, led the authors to conclude that the higher chlorophyllous plants have not the power of taking up elementary nitrogen by means of their leaves, or otherwise. The conclusions arrived at were, that atmospheric nitrogen is not a source of nitrogen in the case of gramineous, cruciferous, chenopodiaceous, or solanceous crops, but with regard to the *Leguminosæ* it was admitted that there was not sufficient evidence to account for the whole of the nitrogen taken up. Of the recent researches bearing on the subject, those of Hellriegel and Wilfarth, first published in 1886, were considered the most striking and conclusive.

In 1883, Hellriegel grew plants of various families in washed sand containing the necessary ash constituents but no nitrogen; in one series nothing further was given, whilst to others varying known amounts of sodium nitrate were added. The gramineous and some other plants of the first series were all limited in growth by the amount of nitrogen contained in the seed, and in the other series the growth was largely proportional to the amount of nitrogen which was applied. On the other hand, whilst most of the peas of the series to which no nitrogen was added failed after a short time, some would develop luxuriantly; and it was found that the roots of the plants of limited growth were free from nodules, and that there was abundant nodule formation on the roots of the well-developed plants. These results led Hellriegel to make further experiments, the results of which showed that leguminous plants will not develop to any extent in sterilized sand free from nitrogen; whilst in the case of peas, vetches, and some other *Papilionaceæ*, the addition of a small quantity of soil extract containing an immaterial amount of nitrogen, causes the plants to grow luxuriantly. A soil extract, prepared from an ordinary soil, which produces such striking results with the plants just mentioned has no effect with lupins. The same result is, however, readily obtained with lupins by the application of a soil extract from a sandy soil in which lupins have been growing. With clover less definite results were obtained for some time, but more recently it has been observed that whilst the extracts from other soils produce little or no effect on clover, an extract from a root-crop soil brought about a considerable nitrogen fixation; but the result was less marked than with the other leguminous plants. In all cases the nitrogen assimilation was accompanied by nodule formation on the roots. Sterilized soil extracts were entirely without effect.

[1] "New Experiments on the Question of the Fixation of Free Nitrogen (Preliminary Notice)," by Sir J. B. Lawes, Bart., LL.D., F.R.S., and Prof. J. H. Gilbert, LL.D., F.R.S. (Proc. Roy. Soc., xlvii. 85).

As stated in a postscript to the paper in the Phil. Trans. already referred to, a preliminary series of pot experiments on similar lines to Hellriegel's was commenced at Rothamsted in 1888. The plants selected were peas, blue lupins, and yellow lupins. They were grown in washed sand containing a small amount (0·0027 per cent.) of nitrogen and the necessary ash constituents; whilst for comparison all the plants were grown in a rich garden soil, and the lupins in a special lupin soil as well. As more normal and satisfactory growth was obtained with peas, only the results relating to these will be discussed here. The lupins, which are admittedly difficult to manage under the artificial conditions which must, more or less, prevail in experiments of this kind, gave no very definite indications in the first year's experiments, although, in 1889, the most striking of the results were those obtained with yellow lupins. Of the peas grown in sand, No. 1 had nothing further added, whilst to Nos. 2 and 3 an extract from the garden soil was added. All the peas germinated and grew well, but about five or six weeks after sowing, the plants of the pots seeded with soil organisms began to acquire a darker colour than those of the pot which was not so seeded, and from this time the plants gained both in leaf surface, and in number of leaflets, and maintained a brighter green colour. At the conclusion of the experiments it was found that the roots of the plants in the unseeded pot had many nodules; the roots of the plants of the seeded pots had many more and much larger nodules than those of the unseeded pot. That these had nodules at all is to be attributed to the impurity and non-sterilization of the sand. The root, too, was much more distributed through the whole of the sand which was seeded than through the sand which was not seeded. The roots of the plants grown in garden soil were very much developed, but showed comparatively few nodules, which were, moreover, smaller than those of the other pots. Owing to the lateness of the season none of the plants flowered.

With regard to the above ground growth at the end of the experiment, there was more vegetable substance produced in the pots seeded with soil organisms than in the unseeded pot; and this increased growth was without doubt connected with the development of the root nodules and their contents. But the greatest gain was in the total nitrogen. In fact, whilst the amount of dry produce in the seeded pots was less than one-fifth more than that of the unseeded pot, there was about twice as much nitrogen in the above ground growth of the seeded, as in that of the unseeded pot. In the case of the garden soil there was more growth, more dry substance, and more nitrogen than in any of the others. In all three pots with sand, the amount of nitrogen in the produce, and in the sand, at the end of the experiment was far greater than that of the seed sown, and the sand, at the commencement. In each case the amount of nitrogen in the sand remained practically unchanged, the gain, therefore, being in the plants. The same may be said of the garden soil, but with some reserve, owing to the great difficulty, to say the least, of detecting slight changes in the amount of nitrogen in a large bulk of rich soil. There is, at least, no evidence to show that either the sand or the garden soil have taken up nitrogen on their own account, independently of the plant.

In order to show clearly that the gain of nitrogen is far beyond the limits of experimental error, it will be well to give some numerical results showing the actual amounts which had to be dealt with. Leaving out of account the difference in the amount of nitrogen of the seeds sown in each pot—the exact amounts are recorded in the paper—and the slight difference in the initial and final amounts of nitrogen in the sand, the results will be as follows:—In the 9 pounds of sand which each pot contained there was nearly 0·1 gram of nitrogen. The three seeds sown in each pot contained nearly 0·03 gram of nitrogen. At the conclusion of the experiment the vegetable produce contained: pot 1, 0·28; pot 2, 0·54; pot 3, 0·44 gram of nitrogen; which, after deducting the nitrogen of the seed sown, corresponds with a gain of 0·25, 0·51, and 0·41 gram of nitrogen.

The experiments in the second season, 1889, included the following leguminous plants: peas, red clover, vetches, blue lupins, yellow lupins, and lucerne. The sand used this time was a coarse, white sand which was well washed and also sufficiently, if not absolutely, sterilized by heating for some days at nearly 100° C. The necessary ash constituents, mixed with an equal weight of calcium carbonate, were added to each pot. There were four pots to each series. No. 1 contained the prepared sand with nothing further added. Nos. 2 and 3 the same sand to which a soil extract was added—prepared from a good garden

soil in the case of all the plants except the lupins, and for these from a special sandy soil from a field in which lupins were growing. No. 4 garden soil, or, for the lupins, the special lupin soil. With regard to the peas and vetches of the pots not seeded with soil extract, the growth was extremely limited, and the colour of the leaves pale green; in the second and third pots of the two series there was luxuriant growth, the plants being taller even than those grown in garden soil. On the other hand, the garden soil plants were more vigorous and produced flower and seed. An examination of the roots of the plants showed an entire absence of nodule formation on those of the pots where no soil extract was given, whilst on the roots of the other plants there was, coincidently with the increased growth, an abundance of nodules. As in the experiments of 1888, the amount of nodules on the roots of the plants grown in garden soil was less than in the sand treated with soil extract.

Still more striking were the results obtained with yellow lupins. Whilst the plants of pot 1 (without soil extract) barely appeared above the rim of the pot, those of pots 2 and 3 (with soil extract) were large branched plants, the largest being 2 feet high—larger even than those grown in the lupin soil. Moreover, unlike the peas and vetches, the yellow lupins grown in sand seeded with soil organisms, flowered and seeded freely. The superiority of these plants over those grown in the lupin sandy soil may be due to the fact that the lupin soil was much less porous than the sand, especially when watered, and perhaps on this account less adapted for favourable growth. The roots of the plants without soil extract seeding were of very limited development and quite free from nodules. In pots 2 and 3, with soil extract seeding, the root development was very great, and the roots showed several large swellings; the ends of the roots were thickly covered with root-hairs, probably indicating an effort to acquire water and mineral nutriment in quantity commensurate with the large amount of nitrogen fixed, and so rendered available to the plant. In the garden soil the root development and nodule formation were much less.

The blue lupins again failed, with the exception of one plant in one pot. The red clover and lucerne are left for further growth. In pot 1 (unseeded) of the lucerne the plants do not appear to have grown at all since a few weeks after the seeds were sown, and for a long time there seemed to be no increased growth in pots 2 and 3, which were seeded with garden soil extract. Pot 2 had, therefore, a fresh quantity of soil extract—this time from a soil where lucerne was growing—added; this also seemed for some time to have no effect, but subsequently there was some increased depth of colour and some increased growth. Pot 3 was watered with a dilute solution of calcium nitrate, which soon produced a very marked and beneficial effect. With regard to the red clover, the results are, as yet, uncertain; both in the pots to which soil extract was added, and in that which had no soil extract, there is much more growth than is believed can be accounted for by nitrogen in the seed sown. The glass house in which the experiments are made stands in the middle of allotment gardens where vegetables of all kinds are grown, and this fact, viewed in the light of Hellriegel and Wilfarth's more recent results, already referred to—according to which the best results with clover are obtained by seeding with organisms from a root-crop soil—points to a possible acquisition of organisms from the air as the most probable explanation.

Attention is drawn to the widely different external appearance of the tubercles of the different plants. In the case of peas, they occurred generally as agglomerations; on the roots of vetches the nodules were generally single. Lupins seem to have two kinds of tubercular development, the most prevalent being "swellings" which entirely encase the thick roots; the "nodules" are generally small, and are distributed on the root-fibres. The lucerne nodules are, again, quite different in form from any of those already mentioned, being long, and generally divided or branched.

Returning to the main object of the investigation, the results confirm those of Hellriegel and Wilfarth, in showing the fixation of free nitrogen under the influence of microbe-seeding of the soil, and the resulting nodule formation on the roots in the case of the leguminous plant.

It appears that, concurrently with the experiments made at Rothamsted, M. Bréal, of the Muséum d'Histoire Naturelle of Paris, has made various experiments instigated by the results of Hellriegel and Wilfarth, and his results also confirm those of Hellriegel.

Hellriegel agrees with the authors that the *Leguminosæ* utilize soil nitrogen. He considers that the soil would be drawn upon first, and that this source is supplemented by the elementary nitrogen of the air, brought into combination by means of the organisms; he also considers that there would be more or less fixation even with a soil rich in nitrogen. On the other hand, Vines found the formation of tubercles, and presumably also the fixation of free nitrogen, is much reduced, or even stopped altogether, by the application of much nitrate to the soil; and the Rothamsted experiments indicate, that with a rich garden soil there are far fewer nodules formed, than with a sand containing but little nitrogen, and seeded with soil organisms. If subsequent experiments should show this to be the case, the amount of nitrogen of a crop, derived from the air, and the amount derived from a soil, would vary very much according to circumstances; fixation would take place most freely in the case of a sandy, or poor and porous soil, and less in a richer soil.

Upon the whole, it is considered that the evidence at command points to the conclusion that, in the case of most, if not all our leguminous crops, more or less of their nitrogen will be due to fixation under the conditions supposed.

Regarding the mode in which the organisms, which, in symbiosis with the higher plants, bring about the fixation, although Marshall Ward, Prażmowski, and Beyerinck have already contributed interesting results as to the mode of life of these bodies, much has yet to be learnt on the subject before an adequate explanation of the phenomena involved can be given. The authors suggest the following alternatives:—"(1) That, somehow or other, the plant itself is enabled, under the conditions of symbiotic life, to fix free nitrogen of the atmosphere by its leaves—a supposition in favour of which there seems to be no evidence whatever. (2) That the parasite utilizes and fixes free nitrogen, and that the nitrogenous compounds formed are taken up by the host. On such a supposition, the actually ascertained large gain of nitrogen by the leguminous plant growing in a nitrogen-free, but properly infected soil, becomes intelligible."

In their former paper (*loc. cit.*) the authors had stated that all the evidence that had been acquired in lines of inquiry previously followed had failed to solve conclusively the question of the sources of the whole of the nitrogen of the *Leguminosæ*, and that hence it should not excite surprise that new light should come from a new line of inquiry.

"The question suggests itself, whether such, or allied agency, comes into play in the nitrogen assimilation of leguminous plants generally, or that of other than the agricultural representatives of the non-leguminous families to which we owe such plants, or of those of the numerous and varied other families of the vegetable kingdom.

"It is true that the families which contribute staple agricultural plants are but few, and that the agricultural representatives of those families are also comparatively few. The families so contributing are, however, among the most important and widely distributed in the vegetable kingdom; as also are some of the plants they contribute. As prominent examples may be mentioned the *Gramineæ*, affording the cereal grains, a large proportion of the mixed herbage of grass-land, and other products; also the *Leguminosæ*, yielding pulse-crops, many useful herbage plants, and numerous other products. As we have said, there does not seem to be an unsolved problem as to the sources of the nitrogen of other of our agricultural plants than those of the leguminous family. Obviously, however, it would be unsafe to generalize in regard to individual families as a whole, from results relating to a limited number of examples supplied by their agricultural representatives alone. Still, there is nothing in the evidence at present at command to point to the supposition that there is any fundamental difference in the source of the nitrogen of different members of the same family, such as is clearly indicated between the representatives of the leguminous, and of the other families, supplying staple agricultural products. On the other hand, existing evidence does not afford any means of judging whether or not similar, or allied agencies to those now under consideration, or even quite different ones, may come into play in the nitrogen assimilation of other families which contribute such a vast variety of vegetation to the earth's surface." N. H. J. M.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—At the meeting of the Philosophical Society, on Monday, May 12, at 4.30 p.m., the following papers are promised:—

Mr. Langley, effect of nicotin on the nervous system of the fresh-water crayfish.

Mr. Shipley, on a new species of Phymosoma, with some account of the geographical distribution of the genus.

Mr. Adami, on the action of the papillary muscles of the heart.

Mr. Harmer, exhibition of specimens of a Land-Planarian (*Rhynchodemus terrestris*, O. F. Müller) found in Cambridge.

SCIENTIFIC SERIALS.

The *American Meteorological Journal* for March contains the conclusion of M. Faye's articles on the theory of storms, based on Redfield's laws. The author maintains that cyclones are descending whirls with a vertical axis, that they originate in the upper currents of the atmosphere, and follow the course of these currents. He considers it very desirable that two different modes of drawing charts should be adopted, to distinguish between cyclones and statical depressions to which, in his opinion, the laws of storms do not in any way apply.—Prof. H. A. Hazen contributes an article on the spectre of the Brocken, and gives a summary of various explanations of the phenomenon. He gives the results of his observations upon a similar shadow seen upon Mount Washington. This number also contains an extract from a paper by Dr. Schenck on the climatic treatment of pulmonary consumption; the advantages of New Mexico, especially, are pointed out.

In the number of the *Journal* for April, M. Faye commences a series of articles on trombes and tornadoes; he deals principally in this number with the theories of various writers and with descriptions of the phenomenon.—Mr. A. H. Dutton analyses the laws laid down by Padre Viñes relative to the normal points of recurvature of West India hurricanes. The result of his inquiry is that less than 14 per cent. of the tropical storms obeyed the laws.—Mr. A. L. Rotch summarizes the proceedings of the International Hydrological Congress held at Paris in October last. The next Congress is to be held in Rome in 1892.

Department of Agriculture, Bulletin No. 4, July 1889 (by authority, Government Printing Office, Melbourne)—This Report embodies the results of State-aided scientific effort which is intended to benefit agriculture, as we sincerely trust it will. The contents are miscellaneous, although all have direct bearing on the theory and practice of agriculture. Reports on horse-breeding, the needs of plants, irrigation, liquorice, yields of milk, vineyards, fruit-culture, Danish dairying, &c., yield a varied diet for the omnivorous reader, and will be of special service to Australian cultivators. We plead guilty to a feeling in connection with the perusal of such *Bulletins* as this, that the work is official, and lacks spontaneity. There is, notwithstanding, much that is valuable. Take, for example, the raisin industry (p. 91). Here we find described the conditions for successful growth, varieties, cultivation, and drying. What can be more useful to a colonist up country than to possess trustworthy information in detail on such a subject? If he is engaged in the wider pursuits of horse or cattle ranching, he will find subject-matter—addresses of breeders, names of sires, and other information of solid value. The *Bulletin* will also be of interest to the increasing class of owners of land in Australia who reside in England, as well as to young men who are thinking of making Australia their home. Anyone writing for this class of information should secure the previous numbers and also the future issues, and these he would probably be able to obtain free of charge by application at the offices of the Agricultural Department at Melbourne, or in London, at the Australian Colonial Offices in Victoria Street.

SOCIETIES AND ACADEMIES.

London.

Royal Society, March 27.—"Measurements of the Amount of Oil necessary in order to check the Motions of Camphor upon Water." By Lord Rayleigh, Sec. R.S.

The motion upon the surface of water of small camphor scrapings, a phenomenon which had puzzled several generations of inquirers, was satisfactorily explained by Van der Mensbrugghe (*Mémoires Couronnés* (4to) of the Belgian Academy, vol. xxxiv., 1869), as due to the diminished surface-tension of water impregnated with that body. In order that the rotations may be lively, it is imperative, as was well shown by Mr. Tomlinson, that the utmost cleanliness be observed. It is a good plan to submit the internal surface of the vessel to a preliminary treatment with strong sulphuric acid. A touch of the finger is usually sufficient to arrest the movements by communicating to the surface of the water a film of grease. When the surface-tension is thus lowered, the differences due to varying degrees of dissolved camphor are no longer sufficient to produce the effect.

It is evident at once that the quantity of grease required is excessively small, so small that under the ordinary conditions of experiment it would seem likely to elude our methods of measurement. In view, however, of the great interest which attaches to the determination of molecular magnitudes, the matter seemed well worthy of investigation; and I have found that by sufficiently increasing the water surface the quantities of grease required may be brought easily within the scope of a sensitive balance.

In the present experiments the only grease tried is olive oil. It is desirable that the material which is to be spread out into so thin a film should be insoluble, involatile, and not readily oxidized, requirements which greatly limit the choice.

Passing over some preliminary trials, I will now describe the procedure by which the density of the oil film necessary for the purpose was determined. The water was contained in a sponge-bath of extra size, and was supplied to a small depth by means of an india-rubber pipe in connection with the tap. The diameter of the circular surface thus obtained was 84 cm. (33"). A short length of fine platinum wire, conveniently shaped, held the oil. After each operation it was cleaned by heating to redness, and counterpoised in the balance. A small quantity of oil was then communicated, and determined by the difference of readings. Two releasements of the beam were tried in each condition of the wire, and the deduced weights of oil appeared usually to be accurate to $\frac{1}{20}$ milligram at least. When all is ready, camphor scrapings are deposited upon the water at two or three places widely removed from one another, and enter at once into vigorous movement. At this stage the oiled extremity of the wire is brought cautiously down so as to touch the water. The oil film advances rapidly across the surface, pushing before it any dust or camphor fragments which it may encounter. The surface of the liquid is then brought into contact with all those parts of the wire upon which oil may be present, so as to ensure the thorough removal of the latter. In two or three cases it was verified by trial that the residual oil was incompetent to stop camphor motions upon a surface including only a few square inches.

The manner in which the results are exhibited will be best explained by giving the details of the calculation for a single case, *e.g.* the second of December 17. Here 0·81 milligram of oil was found to be nearly enough to stop the movements. The volume of oil in cubic centimetres is deduced by dividing 0·00081 by the sp. gr., viz. 0·9. The surface over which this volume of oil is spread is

$$\tfrac{1}{4}\pi \times 84^2 \text{ square centimetres;}$$

so that the thickness of the oil film, calculated as if its density were the same as in more normal states of aggregation, is

$$\frac{0{\cdot}00081}{0{\cdot}9 \times \frac{1}{4}\pi \times 84^2} = \frac{1{\cdot}63}{10^7} \text{ cm.,}$$

or 1·63 micro-millimetres. Other results, obtained as will be seen at considerable intervals of time, are collected in the table.

A Sample of Oil, somewhat decolorized by exposure.

Date.	Weight of oil.	Calculated thickness of film.	Effect upon camphor fragments.
	Mg.		
December 17 ...	0·40	0·81	No distinct effect.
January 11 ...	0·52	1·06	Barely perceptible.
" 14 ...	0·65	1·32	Not quite enough.
December 20 ..	0·78	1·58	Nearly enough.
January 11 ...	0·78	1·58	Just enough.
December 17 ...	0·81	1·63	Just about enough.
" 18 ...	0·83	1·68	Nearly enough.
January 22 ...	0·84	1·70	About enough.
December 18 ...	0·95	1·92	Just enough.
" 17 ...	0·99	2·00	All movements very nearly stopped.
" 20 ...	1·31	2·65	Fully enough.

A Fresh Sample.

January 28 ...	0·63	1·28	Barely perceptible.
,, 28 ...	1·06	2·14	Just enough.

For convenience of comparison they are arranged, not in order of date, but in order of densities of film.

The sharpest test of the quantity of oil appeared to occur when the motions were nearly, but not quite, stopped. There may be some little uncertainty as to the precise standard indicated by "nearly enough," and it may have varied slightly upon different occasions. But the results are quite distinct, and under the circumstances very accordant. The thickness of oil required to take the life out of the camphor movements lies between one and two millionths of a millimetre, and may be estimated with some precision at 1·6 micro-millimetre. Preliminary results from a water surface of less area are quite in harmony.

For purposes of comparison it will be interesting to note that the thickness of the black parts of soap films was found by Messrs. Reinold and Rücker to be 12 micro-millimetres.

An important question presents itself as to how far these water surfaces may be supposed to have been clean to begin with. I believe that all ordinary water surfaces are sensibly contaminated; but the agreement of the results in the table seems to render it probable that the initial film was not comparable with that purposely contributed. Indeed, the difficulties of the experiments proved to be less than had been expected. Even a twenty-four hours' exposure to the air of the laboratory[1] does not usually render a water surface unfit to exhibit the camphor movements.

The thickness of the oil films here investigated is, of course, much below the range of the forces of cohesion; and thus the tension of the oily surface may be expected to differ from that due to a complete film, and obtained by addition of the tensions of a water-oil surface and of an oil-air surface. The precise determination of the tension of oily surfaces is not an easy matter. A capillary tube is hardly available, as there would be no security that the degree of contamination within the tube was the same as outside. Better results may be obtained from the rise of liquid between two parallel plates. Two such plates of glass, separated at the corners by thin sheet metal, and pressed together near the centre, dipped into the bath. In one experiment of this kind the height of the water when clean was measured by 62. When a small quantity of oil, about sufficient to stop the camphor motions, was communicated to the surface of the water, it spread also over the surface included between the plates, and the height was depressed to 48. Further additions of oil, even in considerable quantity, only depressed the level to 38.

The effect of a small quantity of oleate of soda is much greater. By this agent the height was depressed to 24, which shows that the tension of a surface of soapy water is much less than the combined tensions of a water-oil and of an oil-air surface. According to Quincke, these latter tensions are respectively 2·1 and 3·8, giving by addition, 5·9; that of a water-air surface being 8·3. When soapy water is substituted for clean, the last number certainly falls to less than half its value, and therefore much below 5·9.

April 24.—"On a Pneumatic Analogue of the Wheatstone Bridge." By W. N. Shaw, M.A., Lecturer in Physics in the University of Cambridge. Communicated by Lord Rayleigh, Sec. R.S.

When fluid flows steadily through an orifice in a thin plate, the relation between the rate of flow, V, measured in units of volume of fluid per second, and the head H (the work done on unit mass of the fluid during its passage) may be expressed by the equation:—

$$H = RV^2,$$

where R is a constant depending upon the area of the orifice. If the head be measured in gravitation units, R is equal to $1/2gk^2a^2$, where g is the acceleration of gravity, a the area of the orifice, and k the coefficient of contraction of the vein of fluid, a factor which is independent of the rate of flow.

Measurements made upon the flow of air in order to determine the coefficient of contraction have been hitherto such as may be termed "absolute"; that is to say, the head and the flow have each been separately expressed in absolute measure and the value of R determined by taking the ratio of the head to the square of the flow. This process is exactly analogous to measuring the electrical resistance of a wire by finding the electromotive force between its ends and the current which flows along it.

M. Murgue, in a work on "The Theory and Practice of Centrifugal Ventilating Machines" (translated by A. L. Steavenson), has shown that the internal resistance of a centrifugal fan to the flow of air through it can be calculated from the effects produced on the flow by varying the size of a second orifice through which the air had to pass. This process is evidently parallel to calculating the internal resistance of a battery by finding the effects produced upon the current by varying the external resistance. The further development of the analogy seems to afford a "null" method of comparing resistances to the motion of air, and of verifying the laws of flow, and one which requires only a detector and not an anemometer, and is independent of the constancy of the flow. Whether it could be used practically to test the laws of flow and measure the pneumatic constants for various orifices to a higher degree of accuracy than has hitherto been attained, evidently depends upon the sensitiveness of the arrangement. In order to try this, the author constructed what may be called a pneumatic analogue of the Wheatstone Bridge. It consists of three wooden rectangular boxes, A, B_1, B_2. The ends of B_1 and B_2 abut against the side of A; between B_1 and A is a rectangular opening, a_2, 1 in. × ½ in., in a cardboard diaphragm; between B_2 and A a rectangular opening, a_4, 1 in. × 1 in., in a similar diaphragm. In the side of B_1 at a_1 is an adjustable slit, made by cardboard shutters sliding in cardboard grooves, and at a_3 in the side of B_2, opposite to a_1, is a similar adjustable slit. The tube connecting B_1 and B_2, or "galvanometer" tube, is a straight tube of glass, G, of about 1·1 inch internal diameter. It can be closed at one end by a small trap-door in the interior of the box B_1, which can be opened and shut by a steel wire passing through a cork in the top of B_1. The sensitiveness of the apparatus depends upon the indicator employed. There are many indicators that might be suggested; the one tried and found to work well consists of two very small parallel magnetized sewing needles, stuck through a cap of elder-pith, supported on a small agate compass centre; the needles carry very light mica vanes on one side of the centre, counterpoised by a small quantity of platinum wire. The whole is balanced on the point of the finest needle obtainable, and forms a very delicate wind vane. The needles take up a definite position of equilibrium with the planes of the vanes approximately north and south. The apparatus being so placed that the tube, G, is east and west, the vanes always set across the tube when there is no current. The needle-points enable the position of equilibrium to be clearly identified by the aid of a fiducial mark on the glass tube. The sensitiveness can be altered as desired by an external control magnet, just as that of a galvanometer needle can be. The little compass needle or wind vane, M, is very sensitive to the motion of air in the tube.

The head is produced by a gas-burner in a metal chimney fitted to the lid of the box A.

Of the four apertures of the bridge, two, viz. a_2 and a_4, are inaccessible without pulling the arrangement to pieces; they represent areas of ½ sq. in. and 1 sq. in. respectively, as accurately as a knife can cut them in cardboard.

The other two areas, viz. a_1 and a_3, are made by sliding shutters, as already mentioned. The edges were cut with a knife, and they probably are only rough approximations to areas in a truly thin plate.

If the coefficient of contraction may be assumed to be independent of the shape of the orifice, we get the condition for no flow through the "galvanometer" tube:—

$$\frac{a_1}{a_2} = \frac{a_3}{a_4},$$

where the a's represent the actual measured areas of the four orifices.

Observations have been taken with the apparatus—

(1) To verify the law of proportionality of areas, viz.

$$\frac{a_1}{a_2} = \frac{a_3}{a_4}.$$

(2) To verify the inference that the condition of no flow is independent of the total head.

[1] In the country.

(3) To compare a circular with a rectangular aperture.

The observations are sufficient to show that the width of the adjustable slit when there is no flow is a perfectly definite magnitude, and that a properly constructed apparatus is capable of making measurements of the effective areas of orifices with a very considerable degree of precision.

"On the Effect of Tension upon Magnetic Changes of Length in Wires of Iron, Nickel, and Cobalt." By Shelford Bidwell, M.A., F.R.S.

The *iron* used in these experiments was a piece of soft annealed wire, 0·7 mm. in diameter and 10 cm. in length between the clamps. The weights successively attached to it were equivalent to 1950, 1600, 1170, 819, 585, and 351 kilos. per square cm. of section.

The *nickel* wire was 100 mm. long, and 0·65 mm. in diameter. The loads under which it was examined were 2310, 1890, 1400, 980, 700, and 420 kilos. per sq. cm.

The *cobalt* used was a narrow strip measuring 100 mm. by 2·6 mm. by 0·7 mm., its cross section being, therefore, 1·82 sq. mm. It was not possible to obtain this metal in the form of a wire. The loads employed for the strip were equivalent to 772, 344, and 75 kilos. per sq. cm.

In all the experiments the loads were successively applied in decreasing order of magnitude, and before every single observation the wire or strip was demagnetized by reversals, without, of course, being removed from the coil. The magnetizing force was carried up to about 375 C.G.S. units for iron and nickel, and 500 units for cobalt.

The results are given in several tables and curves, and point to the following conclusions:—

Iron.—Tension diminishes the magnetic elongation of iron, and causes contraction to take place with a smaller magnetizing force.

Nickel.—In weak fields the magnetic contraction of nickel is diminished by tension. In fields of more than 140 or 150 units, the magnetic contraction is increased by tensional stress up to a certain critical value, depending upon the strength of the field, and diminished by greater tension.

Cobalt.—The magnetic contraction of cobalt is (for magnetic fields up to 500 G.C.S. units and loads up to 772 kilos. per sq. cm.) practically unaffected by tension.

Chemical Society, April 3.—Dr. Hugo Müller, F.R.S., Vice-President, in the chair.—The following papers were read:—Note on the hydrosulphides, by Messrs. S. E. Linder and H. Picton. The authors find that freshly-precipitated metallic sulphides almost always contain hydrogen sulphide, that they are, in fact, hydrosulphides or remnants of hydrosulphides, and that if, instead of adopting the usual plan of passing gas through the solution, the metallic salt be allowed to run slowly into a solution of hydrogen sulphide in water in the absence of too large an excess of acid, a solution of the hydrosulphide is obtained which can be freed from dissolved hydrogen sulphide by the current of hydrogen. The copper hydrosulphide, $7CuS, H_2S$, and mercury hydrosulphide, $31HgS, H_2S$, are described in the paper.—Researches on the germination of some of the *Gramineæ*, Part I., by H. T. Brown, F.R.S., and Dr. G. H. Morris. This investigation was undertaken with the view of throwing some light on the complex metabolic processes which take place in the germination of seeds. The authors, during the progress of the inquiry, have examined and experimented with the seeds of a great number of the grasses, but this, the first part of their paper, is confined almost entirely to a consideration of the changes which take place in barley during the earlier periods of its growth. In recording the visible changes which occur in the seed during germination, it is shown that a disintegration and dissolution of the cell-walls of the endosperm always precede any attack upon the cell-contents. This breaking down of the cell-wall is shown in a subsequent portion of the paper to depend on the production during germination of a special cellulose-dissolving or "cyto-hydrolytic" enzyme, which, like diastase, is soluble. The action of this enzyme on the cell-walls of some kinds of vegetable parenchyma is very energetic. The physiological importance of this cyto-hydrolyst is very great, for, owing to the non-diffusible nature of the amylo-hydrolytic enzyme—diastase—the previous breaking down of the cell-wall is a necessary prelude to the dissolution of the contained starch-granules. The authors show that the appearance of the cyto- and amylo-hydrolysts is due to a specialized secretory function of the layer of columnar epithelium which covers the outer surface of the scutellum. It has hitherto been considered that the function of this epithelium was exclusively that of an absorptive tissue: its absorptive as compared with its secretory functions are, however, of quite secondary importance. The natural food material—starch—does not appear to have any special power of stimulating the cells of the epithelium to increased secretion of a diastase, but the flow both of diastase and of the cyto-hydrolytic enzyme from these cells is affected in a very remarkable degree by the presence of certain carbohydrates. Providing the carbohydrate is one which is readily assimilable by the embryo, such as cane-sugar or maltose, secretion of ferment is checked or even entirely inhibited. No such inhibitory action is, however, produced by such substances as mannitol and milk-sugar, which are entirely without nutritive value. The authors' experiments in this direction point to the secretion of the amylo-hydrolytic and cyto-hydrolytic enzymes as being to some extent *starvation phenomena*. The power of secretion possessed by the epithelium is in some way or other so adapted to the requirements of the young plant as to be only exercised when the supply of tissue-forming carbon compounds begins to fail. The histological changes which take place in the cells of the epithelium during secretion are very similar to those which have been observed in certain secretory cells of the alimentary tract of animals, and in the secretory cells of some of the insectivorous plants. The authors confirm the important generalization of Sachs, that the relation of the embryo to the endosperm is that of parasite to host, and they have availed themselves of this relation by cultivating the embryo on suitable media after separating it from its endosperm. In this way they have obtained information with regard to the secretory powers of the embryo and the chemical modifications of its absorbed nutriment which it would have been impossible to obtain by any other means. The results of cultivating excised embryos on various nutrient solutions, more especially of the carbohydrates, are recorded, and it is shown that, whilst cane-sugar, invert-sugar, dextrose, lævulose, maltose, raffinose, galactose, and glycerol have all more or less nutrient value, milk-sugar and mannitol do not in any way contribute to the growth of tissue in the young plant. Of all the substances tried, cane-sugar has by far the greatest nutritive power. Maltose, although the natural food of the embryo when attached to its endosperm, is decidedly inferior in this respect to cane-sugar. This, at a later point in the paper, is shown to be due to the fact that maltose, directly it is absorbed by the growing embryo, becomes transformed into cane-sugar by the living cells, and in this form is passed from cell to cell. When cane-sugar is supplied ready formed to the young plantlet, there is manifestly a saving of energy to the living cell, which receives its nutriment in a form in which it is readily available for its requirements. An examination of the sugars produced during germination, and their mode of distribution in the grain, have convinced the authors that the transformed starch of the endosperm is absorbed by the embryo in the form of maltose, and that the seat of production of the cane-sugar which all germinated grain contains is the tissues of the embryo itself. The authors are continuing their work upon the germination of the grasses, and are applying the methods described in this first part of their paper to an elucidation of the chemical changes which the other reserve materials, especially the proteids, undergo in their passage from the endosperm, and of the agencies which are at work in bringing about these transformations. In the discussion which followed the reading of this paper, Prof. Marshall Ward, F.R.S., pointed out that in the seeds of the *Gramineæ*, *Cyperaceæ*, and other families of plants, there is a peculiar layer of cells, from one to three or more deep, surrounding the starchy endosperm, and distinguished from the latter by containing no starch, but relatively large quantities of proteids: this layer belongs to the endosperm, but as the seed ripens, the cells store special proteids instead of the starch-grains which predominate in other endosperm cells. In the oat there is such a layer, one cell deep, and it has been shown that, during germination, the dissolution of the starch and the cell-walls of the starch-containing cells begins near the surface of this layer, which itself persists, and the cells of which take up food and undergo changes so like those of excreting cells that it was concluded that they excrete the diastatic enzyme. Prof. Ward further remarked that the authors' suggestion that more than one enzyme may be excreted according to the nutrition of the cells, and their proof that a cellulose-dissolving enzyme exists in barley, are borne out by various recent researches, and by Wortmann's observations on the behaviour of bacteria in a mixture of starch and proteids. Wortmann proved

that so long as the bacteria were fed with proteids they refused to excrete the diastatic enzyme which they produce in abundance when only carbohydrates are at their disposal. Prof. Green said that in the case of the date-stone his observations led him to believe that the enzyme was independent of the endosperm, and that probably it was located in the epithelial layer. But in castor oil seeds not only the embryo but also the endosperm cells appeared to be possessed of vitality, the fatty matter of the latter undergoing change even when not subject to the action of the embryo; probably the enzyme was present in the form of an enzymogen, as extracts of the seeds were rendered active by acids. Prof. Armstrong remarked that the authors had shown that in the plant maltose was converted into cane-sugar; dextrose, according to their observations, did not undergo conversion into cane-sugar, but gave invert-sugar—that is to say, it became partially converted into lævulose, these constituents of cane-sugar being apparently incapable of interacting. It was known from Emil Fischer's work that dextrose could be converted into lævulose, and that maltose was an etheric compound of the acetal type, formed from two molecules of dextrose, one of which acted as aldehyde, the other as alcohol; it was conceivable that if the "dextrose residue" in maltose underwent a change comparable with that which is involved in the conversion of dextrose into lævulose, a compound would be obtained which if not identical with cane-sugar would be convertible into it by hydration and subsequent dehydration. The authors had spoken of the maltose becoming incorporated with the protoplasm from which the cane-sugar was then elaborated; perhaps the effect was comparable with that exercised by phenylhydrazine in effecting the conversion of dextrose into lævulose through the agency of the osazone. Dr. Lauder Brunton and Mr. Thiselton Dyer also took part in the discussion.—The formation of indene-derivatives from dibrom-α-naphthol, by Prof. R. Meldola, F.R.S., and Mr. F. Hughes.—The action of hydrochloric acid on manganese dioxide; manganese tetrachloride, by Mr. H. M. Vernon. Contrary to the statements of Pickering (Chem. Soc. Trans., 1879, 654), the author finds that the original product of the action of hydrochloric acid on manganese dioxide is manganese tetrachloride, and that at first no free chlorine is formed.

April 17.—Dr. W. J. Russell, F.R.S., President, in the chair.—The following papers were read:—Phosphorous oxide, Part 1, by Prof. T. E. Thorpe, F.R.S., and Mr. A. E. Tutton. The authors describe a method of making phosphorous oxide by burning phosphorus in air. Pure phosphorous oxide crystallizes in thin monoclinic prisms, melts at 22°·5, solidifies at 21°, and boils unchanged in an atmosphere of nitrogen or carbon dioxide at 173°. When heated at 300°, it decomposes, and at 440° is wholly converted into phosphorus and phosphorus tetroxide: $4P_4O_6 = 6P_2O_4 + P_4$. Phosphorous oxide is readily acted on by light, and in bright sunshine its colour rapidly becomes yellow, and eventually dark red, the violet rays being most active in effecting the change. Its molecular weight, as determined by Hofmann's and Raoult's methods, corresponds with the formula P_4O_6; phosphorous oxide, therefore, in this respect is analogous to arsenious and antimonious oxides. The thermal expansion of liquid phosphorous oxide is expressed by the formula—

$$V = 1 + 0·0_3 91377 t - 0·0_6 11175 t^2 + 0·0_8 38607 t^3;$$

its relative density at the boiling-point is 1·6859, whence its molecular volume = 130·5; and its molecular refraction for A ($\lambda = 7604$) at 27°·4 is 60·5. Contrary to the usual statement of the text-books, cold water has very little action on phosphorous oxide: many days elapse before even a small quantity is dissolved; it then forms phosphorous acid. Hot water acts upon it with explosive violence, forming the red sub-oxide, phosphoric acid, and spontaneously inflammable phosphoretted hydrogen. Phosphorous oxide spontaneously oxidizes to phosphorus pentoxide on exposure to air or to oxygen, and the process of oxidation is attended under diminished pressure by a faint luminous glow; ozone is not formed as the oxidation proceeds. On gently warming the oxide in oxygen, the glow gradually increases in intensity until it passes into flame. In contact with ozone, phosphorous oxide glows at the ordinary temperature and pressure. Phosphorous oxide has a well-marked physiological effect, and it is not improbable that the action hitherto attributed to phosphorus, especially as regards its influence on the glycogenic functions of the liver and on tissue change, may be really due to this substance. The fumes from phosphorus consist largely of phosphorous oxide, and the odour of the product obtained by drawing air over phosphorus without allowing it to ignite is identical with that of the pure oxide; it is, indeed, highly probable, as Schönbein long ago surmised, that phosphorus vapour, as such, is odourless, and that the smell which phosphorus ordinarily possesses is a mixture of that of ozone and of phosphorous oxide.—The action of chlorine on water in the light, and the action of light on certain chlorine acids, by Prof. A. Pedler. As a general result of a number of experiments, it is found that, even in very strong tropical sunlight, water and chlorine interact to but a very slight extent when the proportion is about $100\ H_2O : Cl_2$; when the ratio is about $150\ H_2O : Cl_2$ action takes place to the extent of perhaps 50 per cent., and when more than $400\ H_2O : Cl_2$, to about 80 per cent. of the theoretical. Chlorine water containing about $708\ H_2O : Cl_2$ when exposed to direct tropical sunlight decomposes practically entirely in the sense of the equation $2H_2O + 2Cl_2 = O_2 + 4HCl$, an exceedingly small amount of chloric acid being formed; but when exposed in a south aspect to strong diffused daylight, gives much less oxygen and a variable amount of hypochlorous or chloric acids, very little oxygen but an increased amount of hypochlorous or chloric acids being formed when it is exposed in a north aspect to moderate diffused daylight. Hypochlorous acid, on exposure to light in dilute solutions, yields both oxygen and chloric acid, the proportion of oxygen being larger, the greater the intensity of the light. Solutions of chloric acid undergo little or no change. The author concludes that the action of chlorine on water is in its first stage similar to that which it exercises on cold, dilute aqueous potash or soda, and in its second stage to that on more concentrated hot solutions of these alkalis.—Note on the explosion of hydrogen sulphide and of carbon bisulphide with air and oxygen, by the same. The author finds that when a mixture of hydrogen sulphide, air, and oxygen is exploded, a normal result is obtained, sulphur dioxide and water being formed. But when carbon bisulphide vapour is similarly treated, a not inconsiderable proportion of the nitrogen of the air becomes oxidized, and sulphuric compounds are formed under the combined influence of the oxides of nitrogen and sulphur and of the moisture present.—The action of light on phosphorus, and on some of the properties of amorphous phosphorus, by the same. The author brings forward evidence to show that the term "amorphous phosphorus" is a distinct misnomer, and that, so far from the commercial amorphous phosphorus constituting a separate allotropic modification of the element, it is in reality the same substance as the form called rhombohedral or metallic phosphorus; the very slight differences in character noticed between the substances in question being explained by the difference in the state of division and the slight variations conditioned by their mode of formation. The change of red into ordinary phosphorus does not take place below 358°; above this the change takes place *in vacuo*, but exceedingly slowly, even at 445°.—The action of phosphoric anhydride on fatty acids, by Dr. F. S. Kipping. Heptylic acid yields 25–33 per cent. of dihexyl ketone when heated with phosphoric anhydride.

Royal Microscopical Society, April 16.—Dr. C. T. Hudson, F.R.S., President, in the chair.—Mr. J. Mayall, Jun., called attention to a spiral ruling on glass, sent by Mr. P. Braham, of Bath, which had been produced in an ordinary lathe, the diamond point being adjusted on the slide rest; also to a series of photomicrographs of diatoms, sent by Mr. T. Comber. These were of special interest from the fact that they were produced with sunlight, by which the maximum resolving power of the objective was obtained.—Mr. Mayall referred to an improved form of fine-adjustment, constructed and exhibited by Messrs. Powell and Lealand, in which the chief aim had been to construct a fine-adjustment which should combine extreme sensitiveness of action with accuracy and probable durability beyond what had previously been obtained. The essential feature was the application of what watchmakers would term a "jewelled movement." The whole of the contact surfaces by which the fine-adjustment was actuated consisted of polished steel and agate, the intention being to reduce the friction as much as was consistent with steadiness of motion. The result attained was undoubtedly an improvement on the old system, though the cost would probably limit the application to the few instruments required for very special and difficult investigations in microscopy. For high-class photomicrographic work, or where preparations had to be retained under observation for long periods of time, the new mechanism should be particularly useful, for the greater solidity of the general construction clearly pointed to greater

precision and increased stability.—Mr. Goodwin exhibited a form of eye-piece for the microscope which gave a large field with considerable magnifying power.—Mr. A. W. Bennett gave a *résumé* of a paper, by Mr. W. West, on the fresh-water Algæ of North Wales. The paper described a collection of fresh-water Algæ, chiefly diatoms and desmids, made in various localities in North Wales and Anglesey, and it furnished what was beyond comparison the richest list of desmids which had ever been prepared in this country.—Prof. M. M. Hartog's paper, on the state in which water exists in live protoplasm, was read.—A paper descriptive of the method adopted by Mr. Halford in mounting the spermatozoa of the Salmonidæ was read, and specimens in illustration were exhibited by the lantern.—Mr. E. M. Nelson exhibited on the screen several slides showing under high powers (× 1350) the bordered pits of *Pinus* and *Tilia*. He also exhibited a small series of slides to show the qualities of a new apochromatic ¼-in. objective with fluorite lenses and of 95 N.A., which had recently been made by Messrs. Powell and Lealand.—Mr. Mayall mentioned that the gathering which was to have taken place at Antwerp, in celebration of the 300th anniversary of the invention of the microscope, was unavoidably postponed until next year.

Paris.

Academy of Sciences, April 28.—M. Hermite, President, in the chair.—On a class of differential equations of which the general integral is uniform, by M. Emile Picard.—On the characteristic equation of nitrogen, by M. Sarrau. In previous communications the author pointed out that certain experiments with carbonic acid verified an equation analogous to those proposed by Van der Waals and Clausius to represent the relation between the pressure, p, the volume, v, and absolute temperature, T. The following is the equation—

$$p = \frac{RT}{v - \alpha} - \frac{K\epsilon^{-T}}{(v - \beta)^2};$$

where R, α, β, K, and ϵ are constants. A discussion of the experiments made by Regnault and by Amagat on nitrogen shows that its critical point may also be represented by this formula.—On the heats of formation and combustion of several nitrogenous bodies derived from albumenoid matters, by MM. Berthelot and André. The bodies experimented upon are glycollamine or glycocoll, alanine, leucine, tyrosine, asparagine, aspartic acid, and hippuric acid.—Researches on the condensation of benzine and acetylene vapour under the action of the silent discharge, by M. P. Schutzenberger. The benzine condenses into a clear, yellow, resinous solid. Analyses of the liquid employed and of the condensed product are given, and it is shown that the amount of oxygen contained in the latter could not have been taken up from the air, but must have passed through the glass tube.—On *Gomphostrobus heterophylla*, a coniferous prototype from the Permian of Lodève, by M. A. F. Marion.—Observation of Brooks's comet (a 1890) made with the Brunner equatorial at Toulouse Observatory, by M. E. Cosserat.—General theory of the visibility of interference fringes, by MM. J. Macé de Lépinay and Ch. Fabry. The consequences which follow from the theorem demonstrated are pointed out, and it is proposed to describe the experiments which verify them in a future communication.—On the phosphites and the pyrophosphite of lead, note by M. L. Amat.—The action of erythrite upon the alkaline alcoholates, by M. de Forcrand. The author gives a continuation of a previous paper, here discussing formulæ for the bodies discovered and giving thermal data which explain the behaviour of the new substances when heated.—The action of lead oxide upon toluene and the production of benzene, by M. C. Vincent. The paper treats of this reaction at temperatures below the melting-point of lead. The conclusions are drawn: (1) that oxide of lead attacks toluene below 335°, giving water, carbonic anhydride, and benzene; (2) that, at higher temperatures, less benzene and more stilbene and higher hydrocarbons are obtained; (3) that at a red heat, in addition to the above, hydrocarbons produced by the simple heat decomposition of benzene and toluene are obtained; (4) that diphenyl formed during this experiment in small quantity comes rather from the benzene formed by the action of oxide of lead upon the toluene than from benzene contained in the toluene employed.—Thermochemical researches on textile fibres (wool and cotton), by M. Léo Vignon.—Experiments relative to the loss and gain of nitrogen by fallow or cultivated land, by M. A. Pagnoul. The writer finds in the cases examined that the gain of nitrogen in two years is—(1) with bare soil 29 kg. per hectare; (2) with grass land 394 kg. per hectare; (3) with land laid down in clover 904 kg. per hectare.—Note, by M. Ant. Magnin, on the parasitic castration of *Anemone ranunculoides* by *Æcidium leucospermum*.—On the discovery of a giant land tortoise at Mont Léberon, by M. Ch. Depéret.—On the action of the positive pole of a constant galvanic current upon microbes, and particularly upon the anthrax bacillus, by MM. Apostoli and Laquerrière. Among the conclusions drawn are the following: the heating effects of the current may be experimentally neutralized, but the destruction or weakening of vitality of the microbe still takes place; it is the positive pole only which acts upon the microbes, the negative pole and the intermediate space do not give any evidence of adverse action upon the organisms; the current *sui generis* has no effect upon the microbes; the action at the positive pole is due to the disengagement of acids and of oxygen, as will be shown in a further note.—On the existence of tuberculous endocarditis, note by M. Raymond Tripier.

Berlin.

Meteorological Society, April 1.—Prof. Schwalbe, President, in the chair.—Dr. Perlewitz spoke on the influence of the city of Berlin on local climatic conditions. To investigate this he had compared, for the year 1889, the meteorological records of two stations outside the city with those of three inside. As regards temperature, some allowance must be made for the fact that the exposure of the thermometers was not identical at all the stations. The differences in temperature between the city and the surrounding country were greater than for Vienna, the maximal difference showing itself in spring and summer, the minimal in winter. The differences were least at 2 p.m., greater at 7 a.m., and greatest at 9 p.m. The absolute humidity was much less inside the city than in the neighbouring country, and the difference was, as regards maxima and minima, the exact reverse of that which held good for the temperature; whereas, on the other hand, the relative humidity followed the same lines as for differences of temperature. The direction of the wind was generally different in the city from that in the surrounding country, but no definite relationship of the two could be deduced from the observations, and the same held good for the frequency and extent of clouds in the two localities. Thunderstorms were observed less frequently in the city than in the country, but here again it must be borne in mind that the conditions under which observations can be made in the former are much less favourable than for the latter.—Prof. Spörer spoke on the rotation of the sun, and came to the conclusion that the continued endeavours which have been made to determine the rotation of the sun from observations of sun-spots, cannot lead to any definite conclusions.

Physical Society, April 18.—Prof. du Bois-Reymond, President, in the chair.—Prof. Planck spoke on the difference of potential of two binary electrolytes. According to recent views there exists, in any uniform dilute solution of an electrolyte, a complete dissociation of the ions, the latter being in equilibrium, since the sum of the two electricities of the anions and kathions is equal and the osmotic pressure is everywhere the same, quite independently of the nature of the ions. The electrical charge of the ions and the osmotic pressure are the sole forces which are at work in the solution, and suffice to account for all the phenomena which take place inside it. But in order to calculate the above it is necessary to know the mobility of the ions; this has been determined experimentally by Kohlrausch for a large number of different ions, and he has also measured the electrical charge of the ions, this charge being independent of their nature. If the solution is not of uniform composition, the osmotic pressure leads to a movement of the ions from the more to the less concentrated parts of the solution. Now, since the mobility of the ions varies, being five times as great for hydrogen as for chlorine, it follows that a larger number of hydrogen atoms will pass from the more concentrated parts of the solution, than of chlorine. This, however, leads to an upsetting of the electrical equilibrium, and the electrical affinities work in a direction opposite to that of the flow of atoms. The speaker had developed a general mathematical formula to express what takes place in the case of two solutions of different concentrations which are in contact with each other through an intervening porous partition. By means of this formula he has

calculated the magnitude of the differences of potential which establishes itself between the two electrolytes. Applying the formula to a special case, and calculating the difference of potential from the observed rate of flow of the ions and their known electrical charge, he showed that the values thus obtained correspond very closely with those obtained by direct measurement of the difference of potential.

Physiological Society, April 25.—Prof. du Bois-Reymond, President, in the chair.—Dr. Heymans spoke on medullated and non-medullated nerves. The medullary sheath of the former is characterized by the myelin formations which it yields under the action of water and the dark coloration with osmic acid. This last reaction is common to lecithin, protagon, and cholesterin, all of which are found in the medulla. When, however, lecithin has been treated with osmic acid it can no longer be extracted from the nerve, whereas protagon and cholesterin may be extracted by alcohol at 70° C. By taking advantage of this difference in their behaviour it becomes possible to test the statement that lecithin occurs in the neurokeratinous network of the medullary sheath, while protagon and cholesterin are present in the meshes of the network. Experiment does not support the above statement. The speaker had further used the reaction with osmic acid (2 per cent. solution) to investigate the occurrence of non-medullated nerves in certain places in which their presence is a subject of dispute. He found them in the sympathetic and olfactory nerves of the pike, but in much smaller numbers in the former than is usually stated to be the case. In many of the sympathetic fibres he observed a sheath composed of protoplasm which stained brown with osmic acid. He finally discussed fully the transition of medullated cerebrospinal nerves into the non-medullated processes of the ganglia.—Dr. Cowl spoke on methods of recording the variations of blood-pressure in an artery. He criticized the various forms of apparatus in use, and pointed out the errors arising from the use of elastic connections so frequently employed, as a result of which it is impossible to register the exact moment at which the pressure is zero. He had constructed an apparatus in which this source of error is avoided, and which admits of extremely delicate adjustment. He finally exhibited curves to demonstrate the advantages of the newer instrument.

Brussels.

Academy of Sciences, March 1, 1890.—The following were the papers communicated:—Experiments made by Count Espiennes at Scy (Ciney), on the circulation of air during calm nights from the surface of broken ground, by M. F. Folie.—On certain inversions of temperature, and on the frost of September 16, 1887, at Spa, by M. G. Dewalque. In this and the preceding paper it is shown that cold strata of air lie in valleys, and many cases are given of places situated on elevated plateaus where the minimum temperature is habitually higher than that at places of less altitude lying in valleys.—Gustavus Adolphus Hirn, Associate of the Academy, born at Logelbach (Colmar), August 21, 1815, died at the same place, January 14, 1890. An account of his life and work is given by M. F. Folie.—Another obituary notice by M. F. Folie, on C. H. Buys-Ballot, born at Kloetingen, October 10, 1817, died at Utrecht, February 3, 1890.—On phillipsite crystals from sediments found in the centre of the Pacific Ocean, by M. A. F. Renard. In a previous note (February 1890) the physical characteristics and the composition of zeolite crystals from deposits in the Pacific were indicated; the author now shows the conditions under which the phillipsite and mineral matters which accompany it are found.—Determination of the variations in the coefficient and diffusion with temperature for liquids other than water, by M. P. De Heen. The liquids investigated are xylene, benzine, ethyl alcohol, amyl alcohol, amyl benzoate, and carbon bisulphide, at temperatures of 10°, 30°, 50°, 70°, and 90°.—On the nature of the polarizing matter of the beetroot in alcohol; rotatory power of pectous matters, by MM. L. Chevron and A. Droische. It is found pectine and its derivatives exercise an energetic action on polarized light; the rotatory power of these matters is three or four times greater than that of saccharose sugar.—Some properties of conics, by M. C. Servais.—On the centre of curvature of lines described during the displacement of a plane figure in its own plane, by the same author.—Solanidine from potato sprouts; preparation and properties, by M. A. Jorissen.—On semi-invariant functions, by Jacques Deruyts.

Amsterdam.

Royal Academy of Sciences, April 25.—Prof. van de Sande Bakhuysen in the chair.—M. T. Forster read a paper on the influence of smoking on tuberculous matter. He had formerly shown that tuberculous matter does not cease to be infectious after salting. Experiments subsequently made in his laboratory prove that salting *and* smoking do not kill the bacteria of tuberculosis. Not only tuberculous matter, but meat from tuberculous cattle is very infectious.—Prof. van de Sande Bakhuysen communicated an abstract of a paper published by him on an instrument for the determination of the absolute personal error in astronomical transit-observations.

THE ALTERNATE CURRENT TRANSFORMER.

The Alternate Current Transformer in Theory and Practice. By J. A. Fleming, M.A., D.Sc. Vol. I. "The Induction of Electric Currents." Pp. 479. (London: The *Electrician* Printing and Publishing Company, Limited, 1889.)

THE alternating current has of late years sprung into great commercial importance, and accordingly the laws regulating its flow, long known to a few, are becoming recognized and assimilated by the many. The behaviour of alternating currents is so vastly more complex than anything which had to be dealt with in the time-honoured chapter of the text-book concerning "divided circuits" for the case of steady currents, that a new literature has arisen, and a number of half-accepted new terms have been coined.

It is evidently with the aim of making accessible to average readers the greater portion of this subject that Dr. Fleming has put together the above-named book.

The volume is distinctly a compilation, a *réchauffée* of recent work, though it consists partly of a reprint of the author's own articles in the *Electrician*, and it is a compilation of a very useful kind. It brings together a quantity of floating information collected with a keen scent for practically useful items, as well as for topics of contemporary interest.

It is hardly a book to be recommended to the student as a logical treatise. The proof of the laws is a secondary consideration, and though proofs are indicated, it is more to link them on to other things than really to justify and deduce them. In fact the book has the air of being hastily written; but the facts are there, whether deduced rigorously or not, and the practical man, for whom it is written, will not be likely to find fault. In several instances, however, it can be claimed that the presentation of doctrines is as clear as could be wished and as the ability of the author would lead us to expect. Students will undoubtedly be glad of a book which contains so much useful information only accessible otherwise with difficulty.

The early part of the book, dealing with the modern treatment of magnetism, hysteresis, and the like, is fairly good, but is probably now superseded by some still more recent articles by Prof. Ewing himself. The next portion, on simply periodic currents, is very instructive. In it Lord Rayleigh's investigation of the laws of branching for alternating currents is incorporated, and the result applied to determine the correcting factor for a watt-meter; a clear explanation being given of why it is so difficult to measure the average power of an alternating current. Some of Mr. Blakesley's geometrical representations are also utilized; and the whole circumstances of a simply alternating current are very clearly explained.

Then comes an abstract of some of the too-long-buried researches of Prof. Henry, which the recent publication of his memoirs by the Smithsonian Institution has brought into prominence.

A brief account of the experimental investigations of Masson and Breguet, Blaserna, Helmholtz, on transient currents, of Hughes on the induction balance and on the throttling effect of iron wire, follows; together with the Maxwell-Rayleigh-Heaviside theory of the same.

We then come to the main subject of the book—the laws of mutual induction and the theory of induction coils or transformers. Here the author enters into very instructive detail, showing how to deal with transformers containing iron, and incorporating the researches of Hopkinson, Forbes, Sumpner, Ferraris, and Kapp, as well as the general theories of Maxwell and Lord Rayleigh.

A chapter headed "The Dynamical Theory of Current Induction" follows, wherein Prof. Garnett's summary of Maxwell's electro-magnetic ether models is reproduced; some instructive explanations of many Maxwellian ideas is given in a much clearer and more elementary form than is frequent; some experiments and articles of the present writer are incorporated; and lastly, Mr. Tunzelmann's abstract of Hertz's papers is reprinted once more. It is to be regretted that we have not the advantage of a fresh abstract and discussion of these papers by Dr. Fleming himself. So much in Hertz's papers was confessedly crude and tentative that it would have been much more satisfactory to have had a real digest from a contemporary point of view, instead of the useful but now out-of-date summary with which most persons were already familiar.

Perhaps also it may without offence be suggested that a free use of quotation marks in this last chapter, possibly in other chapters also, would not have been out of place. One is a little startled to find whole paragraphs and diagrams incorporated into a book without rather more explicit statement concerning their origin. I may instance pp. 380, 408, 409, among others, as having struck me personally with some surprise, though very likely the feeling was unjustifiable.

It may be useful if I record such trifling slips as I have noticed. Quite possibly some are not erroneous at all. On p. 7 the assertion is made that Faraday "came to see that that which he had denominated the *electrotonic state* is really the amount of electro-magnetic momentum which the circuit possesses." As a matter of history this is surely incorrect? And is there any evidence for the statement on p. 2, that Faraday's failure to obtain current induction in 1825 and 1828 was because his galvanometer circuit was not closed? It seems very improbable. At the bottom of p. 67 the argument seems to me incorrect and confusing. In the diagram on p. 140 *current* should appear as a factor in the lengths OB, BA, &c. On the top of p. 145, there is no need for L and N to be *both* zero in order that the watt-meter factor, F, may equal unity; it is sufficient if the time constant of the fine wire shunt alone vanishes. On p. 209 a p is twice dropped out of an equation. On p. 253 the statement is made "that we may regard the inductance of a conductor as an effect which is due to the fact that the current takes time to penetrate into the conductor"—a statement which is by no means true. And two pages on we read, "as the frequency of alternation is increased, the resultant self-induction of the circuit is lessened, but [? so that] although the true resistance is increased, the impedance may be diminished on the whole." It may, however, be more truly asserted that no

increase in frequency can diminish impedance: it always tends to increase it; and in no case can the impedance of a conductor to alternating currents fall below that felt by steady ones. Both resistance and impedance increase with frequency. It is true that inductance diminishes, but the diminution is very slight except for iron rods. The punctuation of p. 353 has gone somewhat astray.

All these are trifles: the average level of the book is high, and it contains few dull pages. The practical importance and interest of the subject treated is so great that there should be little need to urge students and electrical engineers to make themselves acquainted with it, but I do urge them nevertheless; and they may think it fortunate that Dr. Fleming has managed to find time to issue so instructive and readable and well-timed a volume.

Oliver J. Lodge.

McKENDRICK'S "SPECIAL PHYSIOLOGY."

Special Physiology, including Nutrition, Innervation, and Reproduction. Vol. II. By J. G. McKendrick, M.D., LL.D., F.R.S. (Glasgow: Maclehose and Sons. London: Macmillan and Co. 1889.)

IN the first volume the only purely physiological part was that on muscle, leaving all the rest of the science to be treated of in this volume, which thus includes the physiology of digestion, nutrition, blood and circulation, respiration and the nervous system, as well as reproduction. It is evident that the book must either be of an entirely elementary character, or that the treatment must in parts be extremely inadequate, in order to include all these subjects within the dimensions of a moderate sized volume. As a matter of fact, it lies open to both these objections. In some places the author hampers himself in the treatment of the purely physiological part of the subject by expounding the first elements of chemistry and physics (for the benefit, I suppose, of the average Glasgow student); while other parts, though good, are much too condensed to be understood by the reader who is ignorant of the first principles of science. This disproportion in the treatment of the various subjects meets us at the very beginning of the volume, where twenty pages are devoted to dietetics before any description has been given of the processes of digestion.

In the section on digestion a very good condensed account is given of the theory of secretion. One is surprised, however, to meet with the statement that the submaxillary ganglion can act as a reflex centre. The importance of this view for the physiology of sporadic ganglia is enormous; yet Prof. McKendrick is content with describing Claude Bernard's old experiments, which seemed to support it, and makes no mention of the researches of Bidder and Schiff, made so long ago as 1867, which showed that the secretion obtained in Bernard's experiments was due to recurrent fibres of the chorda tympani, and not to any action of the ganglion as a reflex centre.

The account of the action of the bile on the chyme is not quite accurate. He says: "At the same time the taurocholate of soda throws down the non-peptonized albuminous matters, such as coagulable albumin and syntonin, while the hemialbumose and peptones remain in solution." As a matter of fact, the precipitate consists of parapeptone (syntonin) with a small quantity of peptones.

In describing the formed elements of the blood, no mention is made of the plasma or granule cells. Yet these are daily assuming a larger importance in pathological processes, and every student who is to study medicine should at any rate know of their existence.

In the section on coagulation as fair an account is given of Wooldridge's work on the subject as is possible in the limits of a page and a half; but in his summing up of the differences between this observer and Halliburton, he does not seem to have grasped Wooldridge's theory. He rejects this on the grounds that all Wooldridge's work was done with peptone plasma (which was not the case), and that fibrinogen (Hammarstens) contains no lecithin and can yet clot on addition of lecithin free ferment. That fibrinogen contains no lecithin is, to say the least, extremely doubtful. Bunge states that he has never succeeded in preparing any proteid free from phosphorus. It is practically impossible, however, to form a good judgment on the merits of Dr. Wooldridge's work without reading all his papers on the subject. In none of them has he discussed the question in all its details, and it is probably on this account that his work has been so misunderstood and misrepresented.

It is surprising how few books on physiology mention the *rôle* of the spleen (made so much of by Metschnikoff) as the great *blood-filter*, where all effete blood corpuscles and other deleterious materials are devoured and destroyed by the cells of the splenic pulp. In this volume the rhythmic movements of this organ are fully described, and a long list is given of the extractives that it contains, but its function is left entirely in doubt.

The next two sections, on the circulation and respiration, present the subject fairly completely, and are brief without being obscure. Yet these are not free from some misleading statements. Thus the depressor nerve is included among the afferent nerves that act on the inhibitory or accelerating cardiac centres, so that a student would imagine that stimulation of this nerve lowered the blood-pressure by reflex inhibition of the heart—a mistake one meets with only too often in teaching. Again, in describing the forces concerned in carrying on the circulation through the capillaries, he makes the following statement:—

"Some have supposed that it is supplemented by an attractive influence exerted by the tissues (*vis a fronte*), and the statement is supported by the observation that, when there is an increased demand for blood owing to active nutritional changes, there is an increase in the amount of blood flowing to the part, such as occurs, for example, in the mammary gland during lactation, and in the growth of the stag's horn. Such an attractive influence on the part of the tissues is quite conceivable as a force assisting in the onward flow of blood, acting along with capillarity."

It is rather hard to see how an attractive influence on the part of the tissues can assist in the onward flow of blood, even when it *is* assisted by capillarity. At any rate this statement is sure to be devoured greedily by the studious fool, who will thereafter reproduce it on all possible occasions, probably as the chief factor in the circulation of the blood.

In discussing the nervous mechanism of respiration,

the author confines himself almost entirely to an exposition of Marckwald's views. Apnœa is referred to a hyperoxygenation of the blood, no mention being made of the fact that it may be produced by positive ventilation with any inert gas, and so must be mainly a reflex effect.

Surely, too, in the treatment of the changes in the blood, the researches of Bohr, Blix, and others, on the combination of hæmoglobin with CO_2, were worthy of note.

In the section on the kidney, about 30 pages are devoted to an elaborate description of the normal and abnormal constituents of urine, with their tests and quantitative determination, while the subject of the process of secretion itself is dismissed in the ridiculously small space of three pages.

The final section, on the nervous system, is one of the best parts of the book. Especially good are the pages treating of the special senses. The chapters on the spinal cord and brain are less complete, and present several omissions and errors. Thus no mention is made of the perfectly definite antero-lateral ascending tract, and the knee-jerk is referred to as a true reflex, which is, to say the least, highly dubious. Again, the statement is made that clots in, or lesions of, the corpus striatum cause hemiplegia, whereas this is rarely or never the case unless the internal capsule is also implicated.

Throughout the work the author lies under the disadvantage of having tried to cater for two distinct classes of students, beginners and those who have already a fair general knowledge of the subject. For the former the work is too large and not sufficiently accurate; for the latter, in most parts, too meagre. Still it will be found useful by many of the latter class who have enough critical power to eschew the evil and choose the good, and will serve them as an excellent introduction to the reading of original memoirs. E. H. S.

OUR BOOK SHELF.

I. *Historia Naturalis Itinerum N. M. Przewalskii per Asiam Centralem.* Augustissimus auspiciis sumptibusque ab Societate Imperiali Geographica Rossica edita. Pars Botanica elaboravit C. J. Maximowicz. Volumen I. "Flora Tangutica." Fasciculus 1, Thalamifloræ et Discifloræ. 4to, pp. 110, cum tabulis 31.
II. Volumen II. "Enumeratio Plantarum hucusque in Mongolia nec non in adjacente parte Turkestaniæ Sinensis lectarum." Fasciculus 1, Thalamifloræ et Discifloræ. Pp. 138, cum tabulis 14.

III. *Plantæ Chinenses Potaninianæ nec non Piasezkianæ* (*Acta Horti Petropolitani*, Vol. XI., pp. 1–112). Elaboravit C. J. Maximowicz. (St. Petersburg Botanic Garden, 1889.)

Here are three separate contributions to the flora of Eastern Central Asia, by the well-known authority on the botany of Central and Eastern Asia. It is now nearly forty years since Mr. Maximowicz, through the force of circumstances, had an opportunity of exploring Mandshuria, the results of which he published under the title of "Primitiæ Floræ Amurensis." He was attached as botanist to the Russian frigate *Diana* on a scientific voyage round the world, but in consequence of war breaking out with England and France he was landed in Mandshuria, where he spent three or four years, returning through Siberia and European Russia to St. Petersburg. Subsequently he has visited Japan two or three times, and made large collections of dried plants, and his life, apart from official duties, has been devoted to working out the botany of temperate Asia.

It was known to botanists that he was engaged on the collections made by the renowned Russian explorer Przewalski and others, and we now have the first instalments in a connected form. Many of the novelties he had previously published in the *Mélanges Biologiques* and elsewhere. From the titles cited above, it will be seen that the plan of publication is, if not exactly an ambitious one, at least very laborious, involving much repetition. Possibly such conditions were imposed upon the author. Anyhow, it seems a great pity that the materials were not all worked up in one enumeration. This course would have been far preferable from a practical standpoint, and, what is of greater importance, there would have been a reasonable prospect of its being finished within a few years. With all Mr. Maximowicz's capacity for work, it seems unlikely that he can hope to reach the end on the present elaborate scale. The aggregate of the two quarto publications is 250 pages, and contains the Thalamifloræ and Discifloræ of the collections. At the outside, this is only a sixth of the flowering plants. Then there is the octavo enumeration of Chinese plants brought down to the same point, and this is not the whole of Mr. Maximowicz's botanical work in hand. Recently he issued a monograph of the genus Pedicularis, comprising about 250 species, nearly 100 of which were new, and these mostly Chinese. When it is added that Mr. Maximowicz is a very critical worker, some idea may be formed of the magnitude of the task he has undertaken.

Glancing over the pages we find that the novelties consist almost entirely of new species of old genera, chiefly of those of a wide range, in the northern hemisphere, at least. In fact, only two new genera are described: *Clematoclethra*, near *Actinidia* (which Maximowicz places in the Dilleniaceæ in preference to the Ternstrœmiaceæ), and *Tetraena*, an obscure plant provisionally referred to the Zygophyllaceæ. New genera are more numerous in Dr. Henry's collections from the warm temperate regions of Central and Western China.

W. Botting Hemsley.

Le Glacier de l'Aletsch et le Lac de Märjelen. By Prince Roland Bonaparte. (Paris: Printed for the Author, 1889.)

In this ample pamphlet the author gives an account of the well-known glacier of the Aletsch and the neighbouring mountain region, in the course of which it is incidentally mentioned that the glaciers are again showing signs of increase after a period of general retreat which began in 1854. This statement, I think, requires some qualification, for the Gorner glacier certainly was advancing about the year 1859. The most marked diminution occurred in the next decade, and it did not commence till, at any rate, after 1861. The author describes the curious Märjelen See, which has already been noticed in these pages (vol. xxxvi. p. 612), giving some statistics as to its area, depth, &c. He quotes also a list of the occasions, so far as known, since 1813, on which its waters have escaped beneath the Aletsch glacier. In this, however, there is either an omission or a misprint. It states that in 1859 *le lac se vide*. This may be true, though it seems improbable, for the lake was also drained in 1858. In the latter part of August in that year I saw it for the first time. It was then full. The next evening I again visited the lake. The water had almost all vanished, and the great blocks of ice were stranded on the muddy floor. In reference to this floor the author makes a statement which I fail to understand: "Le bassin du lac est une ancienne moraine de fond d'une des branches du glacier de l'Aletsch. Unless this mud be claimed as *moraine profonde*—and this I should dispute—the assertion seems to me without any valid foundation. The lake lies in the upper part of a small valley, worn by the passage of ice

into a shape something like the pointed half of the bowl of a spoon. Another statement appears to me of questionable accuracy. The author notices the earth pillars on the southern slopes of the Eggishorn, describing them correctly, but saying of them, "Les pyramides des fées, aussi appelées 'blocs perchés.'" Surely this is an unwonted extension of the latter term.

The pamphlet, in short, is rather disappointing. It is beautifully printed on quarto pages with large margins, and is illustrated with three photogravures of glacier scenery, which would be improved by the omission of the human figures, for these by contrast look like negroes in mourning; but it tells us little that is new, and is a "popular" article rather than a scientific memoir.

T. G. BONNEY.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Panmixia.

PRIVATE communications which I have received from naturalists interested in this controversy, and from Mr. Romanes himself, have thrown light on the apparently irreconcilable difference of the views which have been expressed.

I think it desirable that an explanation should be afforded to the readers of NATURE.

When Mr. Romanes contends that cessation of selection leads to a dwindling in the size of a useless organ, he now tells me that he assumes that the mean size of the part in all born (what we may call the birth-mean) was smaller than the mean size of that part in those individuals surviving under selection. Hence the withdrawal of selection substitutes in the adult survivors the lower birth-mean for the former higher selection-mean.

Mr. Romanes had not specifically stated that he made this assumption.

On the other hand, I had—for the purpose of estimating purely and solely the result of panmixia and cessation of selection—assumed that birth-mean and selection-mean were identical, in which case the withdrawal of selection would, of course, not alter the mean.

To assume that birth-mean is smaller than selection-mean in a given case seems to me to be introducing causes other than panmixia or cessation of selection.

It is evident that cases are *possible* in which the mean given by selection is identical with the birth-mean—others in which it is *smaller* than the birth-mean, and others in which it is *larger*. Special causes of a complex character determine whether the ratio is one or the other. If we are to consider the effects of cessation of selection alone, apart from other causes, it seems to me that we must not introduce causes which affect the ratio of birth-mean and selection-mean; we must eliminate them altogether by assuming the ratio to be one of equality. Hence my conclusion that panmixia or cessation of selection alone cannot produce the dwindling of an organ.

If, however, we admit the assumption that the selection-mean is larger than the birth-mean, Mr. Romanes has my full concurrence in stating that cessation of selection leads to dwindling, and I am of course aware that, given that assumption, Weismann and Galton are of the same mind.

The point of interest therefore shifts. The question is, whether we are justified in assuming that in organisms generally in a state of nature the mean size of an organ or part in the selected survivors is larger than in all born, or, to put it fully, larger than would have been the mean size of the part in all born supposing that they had all reached maturity.

I do not think that we have data which warrant this assumption. It is, I think, certain that some cases must sometimes occur in which this is the case, and others in which the selection-mean-size is *smaller* than the birth-mean-size. It is not improbable that in well-established species there is identity of the two means. This is, however, a question which ought to be settled by observation—*not* of domesticated races, but, if possible, of wild forms.

It seems to me that this assumption is precisely what Mr. Darwin considered, and refused to make, so that he avoided attributing dwindling of parts to the cessation of selection. He says ("Origin," 6th ed., p. 401): "If it could be proved that every part of the organization tends to vary in a greater degree towards diminution than augmentation of size, then we should be able to understand how an organ which has become useless would be rendered, independently of the effects of disuse, rudimentary, and would at last be wholly suppressed." Mr. Darwin says, "If it could be proved." This is really the whole point. If the greater size of selection-mean than of birth-mean could have been proved, Mr. Darwin was ready to formulate the doctrine of dwindling by cessation of selection. But, apparently, it could not be proved then. It has not been proved yet. I do not think it at all impossible that it may be proved. The facts are as yet not recorded.

Bertrand's Idiocyclophanous Spar-prism.

IT is a good thing that Prof. Silvanus Thompson has brought the above prism to the notice of the Physical Society (see NATURE, vol. xli. p. 574); it is certainly remarkable that M. E. Bertrand himself has never thought fit to publish any description of his interesting invention. Perhaps it may be worth while to mention a fairly simple method of constructing the prism (which may easily have occurred to others besides myself, and) which has the advantage of requiring only two artificially-worked surfaces, and hence of interfering as little as possible with the natural rhombohedral crystal of Iceland spar.

Four plane, polished faces are required for the prism, which is, in fact, a four-sided parallelopipedon, having two opposite sides parallel to the optic axis, while the two others make an angle of 45° with it.

Now, since in Iceland spar the faces of the natural rhombohedron make angles of very approximately 45° (strictly, 45° 24′) with the optic axis, two of these faces can be utilized for the last-mentioned pair of prism-sides.

Take, then, a cleavage-rhomb of spar, about 1 cm. in thickness, and having edges about 4 cm. in length (Fig. 1); observing

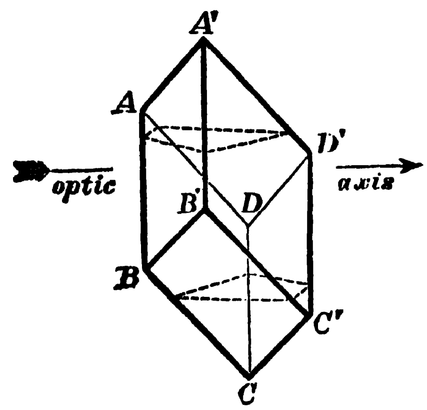

FIG. 1.

that both the face A B C D and the opposite one, A′ B′ C′ D′, are flat and free from blemishes (such a crystal is easily found, even in these spar-famine days). Grind away the solid angle A′ down to about the level shown by the dotted lines, working the face thus obtained so that it makes an angle of 45° with the natural face A B C D. Cut away the opposite solid angle C in a similar way, so as to make another plane, parallel to the first. Polish the two cut surfaces, and the prism is complete in all essential particulars.

Thus, if a beam of common white light is allowed to fall normally on one of the worked surfaces, A, Fig. 2 (which is a section of the prism), it will be (1) totally reflected at the natural face B (corresponding to A B C D in Fig. 1); (2) pass on through the crystal parallel to the optic axis; (3) undergo another total reflexion at the opposite natural face C; and (4) finally emerge through the second worked plane D. An eye placed close to D will then observe the well-known pair of ring-systems side by side, one set complementary to the other.

A very convenient source of illumination seems to be a lamp-

flame within a globular opal shade, placed at such a distance that the three images of it produced by the action of the prism (the centre image formed, of course, by the superposition of two, similarly polarized) just touch each other. Two of these images are then filled (like a lantern-disk) with the complementary ring-systems; and by a very slight motion of the crystal the rings pass from a given disk to the adjacent one, becoming complementary in so doing. (It is hardly necessary to explain, for no doubt Prof. Thompson did so fully, that the whole prism is precisely

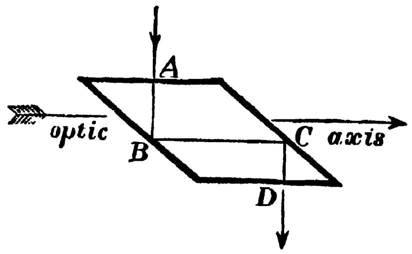

Fig. 2.

equivalent to a train of two double-image prisms with refracting angles of 45°, having between them a plate of spar with surfaces at right angles to the optic axis; a "Huyghens apparatus," in fact, with an interposed spar-plate instead of the usual selenite film.)

I may add that I have found it convenient, in order to demonstrate the principle of the prism, to divide it into halves; or, more strictly, to cut a piece of spar so as to form one half of the prism only, as shown in Fig. 3. Then, if common light from

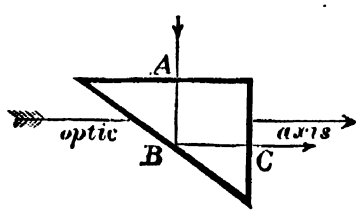

Fig. 3.

the lamp-shade (as described above) is allowed to enter the face A, and a tourmaline is held in the path of the rays emergent from C, ring-systems are seen just as when a double-image prism is used as a polarizer and a plate of spar held in front of it. Also, if plane-polarized light is allowed to enter C, and the eye is held close to A, ring-systems are seen side by side; that portion of the spar through which the rays pass after total reflection at B acting, of course, exactly as a double-image analyzer. In fact, the prism may, in this position, be used alone as a "Savart's polariscope" to detect traces of polarization in sky-light, &c. But for this application, the prism would possess, in the eyes of the true votary of science, the inestimable value of being of no practical utility whatever.

Queen's College, Oxford. H. G. Madan.

Coral Reefs, Fossil and Recent.

Dr. von Lendenfeld's account of the dolomites of the Italian Tyrol, in his letter on "Coral Reefs, Fossil and Recent," is a very valuable contribution to this interesting question; but I think he can hardly have fallen in with the new edition of Darwin's "Coral Reefs," or he would not have asserted that in the discussion "the structure of our Triassic limestone mountains has been left out of account." In the appendix (p. 332) I wrote:—"If those geologists are right who consider the Schlern dolomites as being to a great extent due to reef-building corals, we have, in the Triassic deposits of the Italian Tyrol, reefs thick enough to satisfy the most exacting requirements." I could not venture upon a more positive statement, because I knew controversy on this question was not ended, and I had not myself, though fairly familiar with the "Dolomites," discovered evidence which appeared to me conclusive (though I incline to the above opinion myself), and because I considered that the view advanced several years since by Richthofen required some modification—indeed, as to one detail, if I understand him rightly, I should differ from Dr. von Lendenfeld.

I am confirmed in my idea that he has not read this book, because I find that one of his chief arguments—that against the indefinite lateral extension of a coral reef on a talus of its own building—appears to correspond with one advanced by myself on p. 327, differing only in the addition of an arithmetical example; one of which, indeed, I did work out, but afterwards suppressed as needless, the truth of the statement being obvious when it was once pointed out. T. G. Bonney.

Bison and Aurochs.

In regard to Prof. Newton's letter in your issue of the 8th, I beg to state that in restricting the name aurochs to the European bison, I have merely followed the general custom of English zoologists.

Citing a few authorities, I may first make the following extract from a paper by Prof. W. B. Dawkins, published in the Quart. Journ. Geol. Soc., vol. xxii. p. 394 (1866). There, after alluding to the Indian gaur, this author writes, "the term *Aurochs* has been restricted to the European bison by the authority of Buffon, Cuvier, and Prof. Owen; the term *Urox* or *Bos urus*, to the species under consideration [the extinct wild ox of Europe] by Julius Cæsar, Pliny, . . . also by Cuvier, Nilsson, and our great naturalist, Prof. Owen."

Again, in the article on Ruminants by the late Prof. Garrod in "Cassell's Natural History" (2nd ed., p. 35), the term aurochs is applied to the European bison. Finally, we find in Prof. Flower's "Catalogue of Mammalia in the Museum of the College of Surgeons," p. 232 (1884), the animal in question mentioned as the *European Bison* or *Aurochs*.

I find, however, that modern German zoologists (see Brehm's "Thierleben," vol. iii. p. 386) consider it proved that the name *Aurochs* belongs properly to the extinct *Bos primigenius*; and they term the bison, as Prof. Newton states, the *Wisunt*. If this be really correct, English zoologists must accept the emendation. R. Lydekker.

The Lodge, Harpenden, Herts.

The Haunts of the Gorilla.

Concerning Mr. Du Chaillu's saying (see Nature, May 1, p. 19) "that, so far as he is aware, no white man has been able since his time to penetrate to the haunts of the gorilla and bring home specimens killed by himself," I beg to remark that Herr von Koppenfels, in the years 1873–80, killed personally a number of gorillas in the environs of the Ogowé, and sent 3 large specimens, with their skeletons, to the Dresden Museum, some of which I described in the *Mittheilungen aus dem königl. zoologischen Museum zu Dresden*, vol. ii. 1877, p. 230 *seq*. The Museum in Stuttgart also contains several specimens killed by that intrepid traveller; and other museums, I believe—American museums, for instance—possess some. (See also his remarks in the *American Naturalist*, vol. xv. p. 447; and *Die Gartenlaube*, 1877, p. 416 *seq*., with plate; as well as mine in *Der zoologische Garten*, 1881, vol. xxii. p. 231.) Herr von Koppenfels, who died in the year 1884 in Erfurt, in consequence of diseases acquired in the tropical climate, says (*l.c.*) that the haunts of the gorilla in West Africa are in the forests between the mouths of the Mimi and the Congo Rivers, *i.e.* between 1° N. lat. and 6° S. lat. How far the region extends into the interior is even yet unknown. A. B. Meyer.

Royal Zoological Museum, Dresden, May 7.

Flat-fishes.

Mr. Gulick, in Nature, vol. xli. p. 537, has raised a puzzling point about the flat-fish. In the case of his two Japanese species, it might appear that the ancestor of them both varied in the two directions as to the position of its eyes, &c., and that by the segregation of each form, *neither of which had any advantage over the other*, two species eventually were evolved. But this is not so clear in other cases, apparently. On the American coast of the Pacific, there is a flat-fish, *Paralichthys californicus*, Ayres, which is said by Messrs. Jordan and Goss to be almost as frequently dextral as sinistral. Here, then, is the same sort of variation exactly, yet we see no evidence of segregation and the formation of new species. In the whole subfamily *Soleinæ*, the eyes and colour are on the right side: now, if the "dextral" soles segregated themselves, having no advantage in being dextral rather than sinistral, what has become of all the sinistral ones? If there was no natural selection at play, ought we not to get some sinistral species of *Solea?* Perhaps it may be said that *Solea*, as such, never varied in this way, and was always dextral. But this cannot be so, since we have it on Day's authority that the common sole has a reversed aberration. But, after all, the allied *Cynoglossinæ* are sinistral soles.

Taking the *Pleuronectidæ* as a whole, we certainly get a division into dextral and sinistral groups, which might be supposed to be the result of a "like to like" segregation at an early period. The following table of the sub-families, compiled from Messrs. Jordan and Goss's excellent work on these fishes, illustrates the point :—

(1) *Hippoglossinæ* : normally dextral, except the tropical species, which are sinistral.

(2) *Pleuronectinæ* : sinistral flounders.

(3) *Oncopterinæ* : dextral.

(4) *Platessinæ* : dextral, but *Platichthys stellatus* is frequently sinistral.

(5) *Soleinæ* : dextral soles.

(6) *Cynoglossinæ* : sinistral soles.

But how comes it that the tropical flounders are nearly all sinistral, while the Arctic and Antarctic ones are chiefly dextral?

It would be interesting to know more of the reversed aberrations which occur. *Platessa flesus* var. *passer* (Linn.) is a reversed form, and Day records reversed aberrations of *Solea solea*, *Pleuronectes rhombus*, and *P. maximus*, while others have been noted by various writers. T. D. A. COCKERELL.

Variation in the Nesting-Habits of Birds.

IN connection with T. D. A. Cockerell's letter, *re* the nesting-habits of the blackbird in Colorado, it may be of interest to note that in the grounds around our residence about a fortnight ago, I discovered the nest of a blackbird (*Merula vulgaris*) built upon the ground close to a boundary wall about five feet high. The bottom of the nest is resting on the ground, but there is some trailing ivy growing around—but not on the wall—which supports it at sides and partially obscures it. There is a public road on the other side of the wall and the noise of considerable traffic. There are many suitable trees, bushes, and shrubs, all around, some of which have been utilized by other blackbirds—indeed, there is a tree within a few feet of the nest, which would have been suitable but for the chances of observation from the road. THOS. SWAN.

Bankplace House, Leslie, Fifeshire, Scotland, May 7.

Doppler's Principle.

IN answer to a correspondent who has met with a difficulty in the consideration of Doppler's principle, I may say that I think I fairly solved the difficulty in a paper delivered last year before the University College Chemical and Physical Society. In cases (1) and (2) of your correspondent, viz. approach or recession of observer, source and medium being at rest, the correct formula is $n' = n\frac{a \pm v}{a}$; and in cases (3) and (4), viz. approach and recession of source, observer and medium at rest, it is $n' = n\frac{a}{a \mp v}$, n' = the new, and n the old frequency of vibration of the note heard. It should be remarked, however, that in all practical cases, the two formulæ give very nearly the same result; but if the velocity v is very great, the case is entirely different. Suppose, for instance, in cases (1) and (2) that v = velocity of sound a, then $n' = 2n$ for approach, and 0 for recession of the observer. The correctness of these results is obvious without the aid of any formula. Again, in cases (3) and (4) suppose $v = a$, then $n' = \infty$ for approach, and $\frac{n}{2}$ for recession of the source of sound. The effect of an infinite number of waves striking the ear at the same moment would be simply that nothing would be heard. It would be interesting to notice the change in pitch of the whistle of a rifle-bullet passing near an observer. Ganot's formula is correct for cases (1) and (2), and Prof. Everett's for cases (3) and (4); the proofs are very simple, and may be easily thought out. When the observer and the source of sound both move, the two formulæ should be applied separately when a very accurate result is desired. These conclusions have been confirmed by Dr. Fison, of University College. I had not considered the effect of the motion of the medium, but it appears to me, after a little reflection, that this would increase or diminish the velocity of the sound, and the wave-length, in the same proportion, leaving the pitch unaltered; the velocity of the medium should therefore be added to or subtracted from a in the formula.

University College, May 5. E. P. PERMAN.

"Index Generum et Specierum Animalium."

NATURALISTS have long needed a reference book to the names of genera and species. Such a want has already been partially supplied by Agassiz, Bronn, Morris, Marschall, Scudder, Waterhouse, and others—only Bronn and Morris having attempted palæontological species—but no one book including references to all names given to living and fossil animals has yet been attempted. Botanists, more fortunate, will soon possess Daydon Jackson's index to flowering plants. The idea has therefore suggested itself to me to begin at the end of June next, such an "Index Generum et Specierum Animalium," taking the following rules for guidance :—

(1) The earliest reference is to date from the twelfth edition of Linnæus, 1766.

(2) The last reference to close with December 31, 1899.

(3) The names of genera and species to be given in a single alphabetical sequence, and accompanied by a reference to the original source.

(4) The names of species of each genus to be also quoted in alphabetical order under that genus.

(5) No attempt at synonymy to be given; but, to assist reference, the various genera in which a species has from time to time been placed, to be indicated under that species.

(6) Pre-Linnæan names to be quoted as founded by the author first using them after 1766 :—*e.g. Echinocorys*, Leske, 1778 (*ex* Klein, 1734). Should a pre-Linnæan species or genus have been re-named after 1766, before the post-Linnæan use of that pre-Linnæan name, the new name is to stand. [References will be given to Artedi, Brisson, and Scopoli, in accordance with British Association rules.]

Among the many offers of assistance, that of Prof. Flower, F.R.S., Dr. Günther, F.R.S., and Dr. Henry Woodward, F.R.S., who have promised the necessary space for the storage of the MS. in the Natural History Museum, is most valuable, as it practically ensures safety from fire, and renders the MS. easily accessible to those wishing to consult it while still imperfect.

The contribution of inaugural addresses, theses, or other publications difficult to obtain, would be of great assistance; and, after use, such pamphlets would be handed over to the library at the Museum.

Any suggestions for the improvement of this plan, before the commencement of the undertaking, would be gladly received and carefully considered.

Appended is a rough outline of the scheme :—

"The Anatomy of the Frog."

IN your notice of the above work, in NATURE of the 8th inst., you are pleased to express a favourable opinion of the wood engravings. As the heading of the article might lead your readers to imagine that these, in addition to the coloured plates, were all executed by Hofmann, of Bavaria, I think they, as well as yourself, will be pleased to know that all the *new* blocks, numbering upwards of one hundred, were engraved by

172 Strand, London. T. P. COLLINGS.

COLOUR-VISION AND COLOUR-BLINDNESS.[1]

IT is a matter of familiar knowledge that the sense of vision is called into activity by the formation, on the retina or internal nervous expansion of the eye, of an inverted optical image of external objects—an image precisely analogous to that of the photographic camera. The retina lines the interior of the eyeball over somewhat more than its posterior hemisphere. It is a very delicate transparent membrane, about one-fifth of a millimetre in thickness at its thickest part, near the entrance of the optic nerve, and it gradually diminishes to less than half that thickness at its periphery. It is resolvable by the microscope into ten layers, which are united together by a web of connective tissue, which also carries blood-vessels to minister to the maintenance of the structure. I need only refer to two of these layers: the anterior or fibre-layer, mainly composed of the fibres of the optic nerve, which spread out radially from their point of entrance in every direction, except where they curve around the central portion of the membrane; and the perceptive layer, which, as viewed from the interior of the eyeball, may be likened to an extremely fine mosaic, each individual piece of which is in communication with a nerve fibre, by which the impressions made upon it are conducted to the brain. The terminals of the perceptive layer are of two kinds, called respectively rods and cones; the former, as the name implies, being cylindrical in shape, and the latter conical. The bases of the cones are directed towards the interior of the eye, so as to receive the light; and it is probable that each cone may be regarded as a collecting apparatus, calculated to gather together the light which it receives, and to concentrate this light upon its deeper and more slender portion, or posterior limb, which is believed to be the portion of the whole structure which is really sensitive to luminous impressions. The distribution of the two elements differs greatly in different animals; and the differences point to corresponding differences in function. The cones are more sensitive than the rods, and minister to a higher acuteness of vision. In the human eye, there is a small central region in which the perceptive layer consists of cones only, a region which the fibres avoid by curving round it, and in which the other layers of the retina are much thinner than elsewhere, so as to leave a depression, and are stained of a lemon-yellow colour. In a zone immediately around this yellow spot each cone is surrounded by a single circle of rods; and, as we proceed outwards towards the periphery of the retina, the circle of rods around each cone becomes successively double, triple, quadruple, or even more numerous. The yellow spot receives the image of the object to which the eye is actually directed, while the images of surrounding objects fall upon zones which surround the yellow spot; and the result of this arrangement is that, generally speaking, the distinctness of vision diminishes in proportion to the distance of the image of the object from the retinal centre. The consequent effect has been well described by saying that what we see resembles a picture, the central part of which is exquisitely finished, while the parts around the centre are only roughly sketched in. We are conscious that these outer parts are there; but, if we desire to see them accurately, they must be made the objects of direct vision in their turn.

The indistinctness with which we see lateral objects is so completely neutralized by the quick mobility of the eyes, and by the manner in which they range almost unconsciously over the whole field of vision, that it seldom or never forces itself upon the attention. It may be conveniently displayed by means of an instrument called a perimeter, which enables the observer to look steadily at a central spot, while a second spot, or other object, is moved along an arc, in any meridian, from the circumference of the field of view towards the centre, or *vice versâ*. Slight differences will be found between individuals; but, speaking generally, a capital letter one-third of an inch high, which is legible by direct vision at a distance of sixteen feet, and is recognizable as a dark object at 40° or 50° from the fixing point, will not become legible, at a distance of one foot, until it arrives within about 10°.

The image formed upon the retina is rendered visible by two different conditions—that is to say, by differences in the amount of light which enters into the formation of its different parts, and by differences in the quality of this light, that is, in its colour. The former conditions are fulfilled by an engraving, the latter by a painting. It is with the latter conditions only, and with the power of perceiving them, that we are concerned this evening.

Before such an audience as that which I have the honour to address, it is unnecessary to say more about colour than that it depends upon the power, possessed by the objects which we describe as coloured, to absorb and retain certain portions of white or other mixed light, and to reflect or transmit other portions. The resulting effect of colour is the impression produced upon the eye or upon the brain by the waves of light which are left, after the process of selective absorption has been accomplished. Some substances absorb two of the three fundamental colours of the solar spectrum, others absorb one only, others absorb portions of one or more. Whatever remains is transmitted through the media of the eye; and, in the great majority of the human race, suffices to excite the retina to a characteristic kind of activity. Few things are more curious than the multitude of different colour sensations which may be produced by the varying combinations of the three simple elements, red, green, and violet; but this is a part of the subject into which it would be impossible for me now to enter, and with which most of those who hear me must already be perfectly familiar.

Apart from the effect of colour as one of the chief sources of beauty in the world, it is manifest that the power of distinguishing it adds greatly to the acuteness of vision. Objects which differ from their surroundings by differences of colour are far more conspicuous than those which differ only by differences of light and shade. Flowers are much indebted to their brilliant colouring for the visits of the insects by which they are fertilized; and creatures which are the prey of others find their best protection in a resemblance to the colours of their environment. It is probably a universal truth that the organs of colour-perception are more highly specialized, and that the sense of colour is more developed, in all animals, in precise proportion to the general acuteness of vision of each.

From a variety of considerations, into which time will not allow me to enter, it has been concluded that the sense of colour is an endowment of the retinal cones, and that the rods are sensitive only to differences in the quantity of the incident light, without regard to its quality. Nocturnal mammals, such as mice, bats, and hedgehogs, have no cones; and cones are less developed in nocturnal birds than in diurnal ones. Certain limitations of the human colour sense may almost be inferred from the anatomy of the retina. It is found, as that anatomy would lead us to suppose, that complete colour sense exists only in the retinal centre, or in and immediately around the yellow spot region, and that it diminishes as we pass away from this centre towards the periphery. The precise facts are more difficult to ascertain than might be supposed; for, although it is easy to bring coloured objects from the circumference to the centre of the field of vision on the perimeter, it is by no means easy to be quite sure of the point at which the true colour of the advancing

[1] Lecture delivered at the Royal Institution, on Friday, May 9, 1890, by Mr. R. Brudenell Carter.

object can first be said to be distinctly seen. Much depends, moreover, on the size of this advancing object; because, the larger it is, the sooner will its image fall upon some of the more sparsely distributed cones of the peripheral portion of the retina. Testing the matter upon myself with coloured cards of the size of a man's visiting card, I find that I am conscious of red or blue at about 40° from the fixing point, but not of green until it comes within about 30°; while, if I take three spots, respectively of bright red, bright green, and bright blue, each half a centimetre in diameter, and separated from its neighbour on either side by an interval of half a centimetre, spots which would be visible as distinct and separate objects at eight metres, I cannot fairly and distinctly see all three colours until they come within 10° of the centre. Beyond 40°, albeit with slight differences between individuals, and on different meridians for the same individual, colours are only seen by the degree of their luminosity—that is, they appear as light spots if upon a dark ground, and as dark spots if upon a light ground. Speaking generally, therefore, it may be said that human vision is only trichromatic, or complete for the three fundamental colours of the solar spectrum, over a small central area, which certainly does not cover more than 30° of the field; that it is bi-chromatic, or limited to red and violet, over an annulus outside this central area; and that it is limited to light and shade from thence to the outermost limits of the field.

The nature and limitations of the colour-sense in man long ago suggested to Thomas Young that the retina might contain three sets of fibres, each set capable of responding to only one of the fundamental colours; or, in other words, that there are special nerve fibres for red, special nerve fibres for green, and special nerve fibres for violet. It has also been assumed that the differences between these fibres might essentially consist in the ability of each set to respond only to light-vibrations of a certain wave-length, much as a tuned string will only respond to a note with which it is in unison. In the human subject, so far as has yet been ascertained, no optical differences between the cones are discoverable; but the analogy of the ear, and the facts which have been supplied by comparative anatomy, combine to render Young's hypothesis exceedingly probable, and it is generally accepted, at least provisionally, as the only one which furnishes an explanation of the facts. It implies that elements of all three varieties are present in the central portion of the retina; that elements sensitive to green are absent from an annulus around the centre; and that the peripheral portions are destitute of any elements by which colour-sense can be called into activity.

According to the observation already made, that the highest degree of acuteness of vision is necessarily attended by a corresponding acuteness of colour-sense, we should naturally expect to find such a highly-developed colour-sense in birds, many of which appear, as regards visual power, to surpass all other creatures. I need not dwell upon the often-described acuteness of vision of vultures, or upon the vision of fishing birds; but may pass on to remark that the acuteness of their vision appears not only to be unquestionable, but also to be much more widely diffused over the retina than is the case with man. If we watch domestic poultry, or pigeons, feeding, we shall frequently see a bird, when busily picking up food immediately in front of its beak, suddenly make a lateral dart to some grain lying sideways to its line of sight, which would have been practically invisible to a human eye looking in the same direction as that of the fowl. When we examine the retina the explanation both of the acuteness of vision and of its distribution becomes at once apparent. In birds, in some reptiles, and in fishes, not only are cones distributed over the retina much more abundantly and more evenly than in man, but the cones are provided with coloured globules, droplets of coloured oil, at their apices, through which the light entering them must pass before it can excite sensation, and which are practically impervious to any colour but their own. Each globule is so placed as to intervene between what is regarded as the collecting portion of the cone and what is regarded as its perceptive portion in such a way that the latter can only receive colour which is capable of passing through the globule. The retinæ of many birds, especially of the finch, the pigeon, and the domestic fowl, have been carefully examined by Dr. Waelchli, who finds that near the centre green is the predominant colour of the cones, while among the green cones red and orange ones are somewhat sparingly interspersed, and are nearly always arranged alternately, a red cone between two orange ones, and *vice versâ*. In a surrounding portion, called by Dr. Waelchli the red zone, the red and orange cones are arranged in chains, and are larger and more numerous than near the yellow spot; the green ones are of smaller size, and fill up the interspaces. Near the periphery the cones are scattered, the three colours about equally numerous and of equal size, while a few colourless cones are also seen. Dr. Waelchli examined the optical properties of the coloured cones by means of the micro-spectroscope, and found, as the colours would lead us to suppose, that they transmitted only the corresponding portions of the spectrum; and it would almost seem, excepting for the few colourless cones at the peripheral part of the retina, that the birds examined must have been unable to see blue, the whole of which would be absorbed by their colour globules. It would be necessary to be thoroughly acquainted with their food in order to understand any advantage which the birds in question may derive from the predominance of green, red, and orange globules over others; but it is impossible to consider the structure thus described without coming to the conclusion that the birds in which it exists must have a very acute sense of the colours corresponding to the globules with which they are so abundantly provided, and that this colour-sense, instead of being localized in the centre, as in the human eye, must be diffused over a very large portion of the retina. Dr. Waelchli points out that the coloration of the yellow spot in man must, to a certain extent, exclude blue from the central and most sensitive portion of his retina.

It is hardly necessary to mention how completely the high differentiation of the cones in the creatures referred to tends to support the hypothesis of Young, that a similar differentiation, although not equally manifest, exists also in man. If this be so, we must conclude that the region of the yellow spot contains cones, some of which are capable of being called into activity by red, others by green, and others by violet; that a surrounding annulus contains no cones sensitive to green, but such as are sensitive to red or to violet only; and that, beyond and around this latter region, such cones as may exist are not sensitive to any colour, but, like the rods, only to differences in the amount of light. When cones of only one kind are called into activity, the sensation produced is named red, green, or violet; and, when all three varieties are stimulated in about an equal degree, the sensation produced is called white. In the same way, the innumerable intermediate colour-sensations of which the normal eye is susceptible, must be ascribed to stimulation of the three varieties of cones in unequal degrees.

The conditions of colour-sense which, in the human race, or at least in civilized man, exist normally in outer zones of the retina, are found, in a few individuals, to exist also in the centre. There are persons in whom the region of the yellow spot is absolutely insensitive to colour, and recognizes only differences in the amount or quantity of light. To such persons, the term "colour-blind" ought perhaps in strictness to be limited; but the individuals in question are so rare that they are hardly

entitled to a monopoly of an appellation which is conveniently applied also to others. The totally colour-blind would see a coloured picture as if it were an engraving, or a drawing in black and white, and would perceive differences between its parts only in the degree in which they differed in brightness.

A more common condition is the existence, in the centre of the retina, of a kind of vision like that which normally exists in the zone next surrounding it—that is, a blindness to green. Persons who are blind to green appear to see violet and yellow much as these are seen by the normal-sighted; and they can see red, but they cannot distinguish it from green. Others, and this form is more common than the preceding, are blind to red; and a very small number of persons are blind to violet. Such blindness to one of the fundamental colours may be either complete or incomplete—that is to say, the power of the colour in question to excite its proper sensation may be either absent or feeble. In some cases, the defect is so moderate in degree as to be adequately described by the phrase "defective colour-sense."

The experiments of Helmholtz upon colour led him to supplement the original hypothesis of Young by the supposition that the special nerve elements excited by any one colour are also excited in some degree by each of the other two, but that they respond by the sensation appropriate to themselves, and not by that appropriate to the colour by which they are thus feebly excited. This, which is often called the Young-Helmholtz hypothesis, assumes that the pure red of the spectrum, while it mainly stimulates the fibres sensitive to red, stimulates in a less degree those which are sensitive to green, and in a still less degree those which are sensitive to violet, the resulting sensation being red. Pure green stimulates strongly the green-perceptive fibres, and stimulates slightly both the red-perceptive and the violet-perceptive—resulting sensation, green. Pure violet stimulates strongly the violet-perceptive fibres, less strongly the green-perceptive, least strongly the red-perceptive—resulting sensation, violet. When all three sets of fibres are stimulated at once, the resulting sensation is white; and when a normal eye is directed to the spectrum, the region of greatest luminosity is in the middle of the yellow; because, while here both the green-perceptive and the red-perceptive fibres are stimulated in a high degree, the violet-perceptive are also stimulated in some degree.

According to this view of the case, the person who is red-blind, or in whom the red-perceptive fibres are wanting or paralyzed, has only two fundamental colours in the spectrum instead of three. Spectral red, nevertheless, is not invisible to him, because it feebly excites his green-perceptive fibres, and hence appears as a saturated green of feeble luminosity; saturated, because it scarcely at all excites the violet-perceptive fibres. The brightest part of the spectrum, instead of being in the yellow, is in the blue-green, because here both sets of sensitive fibres are stimulated. In the case of the green-blind, in whom the fibres perceptive of green are supposed to be wanting or paralyzed, the only stimulation produced by spectral green is that of the red-perceptive and of the violet-perceptive fibres; and where these are equally stimulated, we obtain the white of the green-blind, which, to ordinary eyes, is a sort of rose-colour, a mixture of red and violet. In like manner, the white of the red-blind is a mixture of green and violet; and, if we consider the facts, we shall see that spectral red, which somewhat feebly stimulates the green-perceptive fibres of the normal eye, and spectral green, which somewhat feebly stimulates the red-perceptive fibres of the normal, and also of the green-blind eye, must appear to the green-blind to be one and the same colour, differing only in luminosity, and that in an opposite sense to the perception of the red-blind. In other words, red and green are undistinguishable from each other, as colours, alike to the red-blind and to the green-blind; but to the former the red, and to the latter the green, appears, as compared with the other, to be of feeble luminosity. In either case, the two are only lighter and darker shades of the same colour. The conditions of violet-blindness are analogous, but the defect itself is very rare; and, as it is of small industrial importance, it has attracted but a small degree of attention.

Very extensive investigations, conducted during the last few years both in Europe and in America, have shown that those which may be called the common forms of colour-blindness, the blindness to red and to green, exist in about four per cent. of the male population, and in perhaps one per thousand of females. Among the rest, there are slight differences of colour-sense, partly due to differences of habit and training, but of little or no practical importance. One such difference, to which Lord Rayleigh was the first to direct attention, has reference to yellow. The pure yellow of the spectrum may, as is generally known, be precisely matched by a mixture of spectral red with spectral green; but the proportions in which the mixture should be made differ within certain limits for different people. The difference must, I think, depend upon differences in the pigmentation of the yellow spot, rather than upon any defect in the nervous apparatus of the colour-sense. There is a very ingenious instrument, invented by Mr. Lovibond, and called by him the "tintometer," which allows the colour of any object to be accurately matched by combinations of coloured glass, and to be expressed in terms of the combination. In using this instrument, we not only find slight differences in the combinations required by different people, but also in the combinations required by the two eyes of the same person. Here, again, I think the differences must be due either to differences in the pigmentation of the yellow spot, or possibly also to differences in the colour of the internal lenses of the several eyes, the lens, as is well known, being usually somewhat yellow after middle age. The differences are plainly manifest in comparing persons all of whom possess tri-chromatic vision, and are not sufficient in degree to be of any practical importance.

Taking the ordinary case of a red-blind or of a green-blind person, it is interesting to speculate upon the appearance which the world must present to them. Being insensible to one of the fundamental colours of the spectrum, they must lose, roughly speaking, one-third of the luminosity of Nature; unless, as is possible, the deficiency is made good to them by increased acuteness of perception to the colours which they see. Whether they see white as we see it, or as we see the mixtures of red and violet, or of green and violet, which they make to match with it, we can only conjecture, on account of the inadequacy of language to convey any accurate idea of sensation. We have all heard of the blind man who concluded, from the attempts made to describe scarlet to him, that it was like the sound of a trumpet. If we take a heap of coloured wools, and look at them first through a glass of peacock-blue, by which the red rays are filtered out, and next through a purple glass, by which a large proportion of the green will be filtered out, we may presume that, under the first condition, the wools will appear much as they would do to the red-blind; and, under the second, much as they would do to the green-blind. It will be observed that the appearances differ in the two conditions, but that, in both, red and green are practically undistinguishable from each other, and appear as the same colour, but of different luminosity.

Prior to reflection, and still more, prior to experience, we should be apt to conjecture that the existence of colour-blindness in any individual could not remain concealed, either from himself or from those around him; but such a conjecture would be directly at variance with the truth. Just as it was reserved for Mariotte, in the reign of Charles II., to discover that there is, in the field of vision of every eye, a lacuna or blind spot, correspond-

-ing with the entrance of the optic nerve, so it was reserved for a still later generation to discover the existence of so common a defect as colour-blindness. The first recorded case was described to Dr. Priestley by Mr. Huddart, in 1777, and was that of a man named Harris, a shoemaker at Maryport in Cumberland, who had also a colour-blind brother, a mariner. Soon afterwards, the case of Dalton, the chemist, was fully described, and led to the discovery of other examples of a similar kind. The condition was still, however, looked upon as a very exceptional one; insomuch that the name of "Daltonism" was proposed for it, and is still generally used in France as a synonym for colour-blindness. Such use is objectionable, not only because it is undesirable thus to perpetuate the memory of the physical infirmity of an eminent philosopher, but also because Dalton was a red-blind, so that the name could only be correctly applied to his particular form of defect.

Colour-blindness often escapes detection on account of the use of colour-names by the colour-blind in the same manner as that in which they hear them used by other people. Children learn from the talk of those around them, that it is proper to describe grass as green, and bricks or cherries as red; and they follow this usage, although the difference may appear to them so slight that their interpretation of either colour-name may be simply as a lighter or darker shade of the other. When they make mistakes, they are laughed at, and thought careless, or to be merely using colour-names incorrectly; and a common result is that they rather avoid such names, and shrink from committing themselves to statements about colour. Dr. Joy Jefferies gives an interesting description of the almost unconscious devices practised by the colour-blind in this way. He says:—

"The colour-blind, who are quick-witted enough to discover early that something is wrong with their vision by the smiles of their listeners when they mention this or that object by colour, are equally quick-witted in avoiding so doing. They have found that there are names of certain attributes they cannot comprehend, and hence must let alone. They learn, also, what we forget, that so many objects of every-day life always have the same colour, as red tiles or bricks, and the colour names of these they use with freedom; whilst they often, even unconsciously, are cautious not to name the colour of a new object till they have heard it applied, after which it is a mere matter of memory stimulated by a consciousness of defect. I have often recalled to the colour-blind their own acts and words, and surprised them by an exposure of the mental jugglery they employed to escape detection, and of which they were almost unaware, so much had it become matter of habit. Another important point is, that as violet-blindness is very rare, the vast majority of defective eyes are red or green blind. These persons see violet and yellow as the normal-eyed, and they naturally apply these colour-names correctly. When, therefore, they fail in red or green, a casual observer attributes it to simple carelessness hence a very ready avoidance of detection. It does not seem possible that anyone who sees so much correctly, and whose ideas of colour so correspond with our own, cannot be equally correct throughout, if they will but take the pains to notice and learn."

When the colour-blind are placed in positions which compel them to select colours for themselves and others, or when, as sometimes happens, they are not sensitive with regard to their defect, but rather find amusement in the astonishment which it produces among the colour-seeing, the results which occasionally follow are apt to be curious. They have often been rendered still more curious, by having been the unconscious work of members of the Society of Friends. Colour-blindness is a structural peculiarity, constituting what may be called a variety of the human race; and, like other varieties, it is liable to be handed down to posterity. Hence, if the variety occurs in a person belonging to a community which is small by comparison with the nation, and among whose members there is frequent inter-marriage, it has an increased probability of being reproduced; and thus, while many of the best known of the early examples of colour-blindness, including that of Dalton himself, were furnished by the Society of Friends, the examinations of large numbers of scholars and others, conducted during the last few years, have shown that, in this country, colour-blindness is more common among Jews than among the general population. The Jews have no peculiarities of costume; but the spectacle, which has more than once been witnessed, of a venerable Quaker who had clothed himself in bright green or in vivid scarlet, could scarcely fail to excite the derision of the unreflecting. Time does not allow me to relate the many errors of the colour-blind which have been recorded; but there is an instance of a clerk in a Government office, whose duty it was to tick certain entries, in relation to their subject-matter, with ink of one or of another colour, and whose accuracy was dependent upon the order in which his ink-bottles were ranged in front of him. This order having been accidentally disturbed, great confusion was produced by his mistakes, and it was a long time before these were satisfactorily accounted for. An official of the Prussian Post-Office, again, who was accustomed to sell stamps of different values and colours, was frequently wrong in his cash, his errors being as often against himself as in his favour, so as to exclude any suspicion of dishonesty. His seeming carelessness was at last explained by the discovery of his colour-blindness, and he was relieved of a duty which it was impossible for him to discharge without falling into error.

The colour-mistakes of former years were, however, of little moment when compared with those now liable to be committed by engine-drivers and mariners. The avoidance of collisions at sea and on railways depends largely on the power promptly to recognize the colours of signals; and the colours most available for signalling purposes are red and green, or precisely those between which the sufferers from the two most common forms of colour-blindness are unable with any certainty to discriminate. About thirteen years ago there was a serious railway accident in Sweden, and, in the investigation subsequent to this accident, there were some remarkable discrepancies in the evidence given with regard to the colour of the signals which had been displayed. Prof. Holmgren, of the University of Upsala, had his attention called to this discrepancy, and he found, on further examination, that the witness whose assertions about the signals differed from those of other people was actually colour-blind. From this incident arose Prof. Holmgren's great interest in the subject, and he did not rest until he had obtained the enactment of a law under which no one can be taken into the employment of a Swedish railway until his colour-vision has been tested, and has been found to be sufficient for the duties he will be called upon to perform. The example thus set by Sweden has been followed, more or less, by other countries, and especially, thanks to the untiring labours of Dr. Joy Jeffries, of Boston, by several of the United States; while at the same time much evidence has been collected to show the connection between railway and marine accidents and the defect.

It has been found, by very extensive and carefully conducted examinations of large bodies of men, soldiers, policemen, the workers in great industrial establishments, and so forth, as well as of children in many schools, that colour-blindness exists in a noticeable degree, as I have already said, in about four per cent. of the male industrial population in civilized countries, and in about one per thousand of females. Among the males of the more highly educated classes, taking Eton boys as an example, the colour-blind are only between two and three per cent., and perhaps nearer to two than to three.

Whether a similar difference exists between females of different classes, we have no statistics to establish. The condition of colour-blindness is absolutely incurable, absolutely incapable of modification by training or exercise, in the case of the individual; although the comparative immunity of the female sex justifies the suggestion that it may possibly be due to training throughout successive generations, on account of the more habitual occupation of the female eyes about colour in relation to costume. However this may be, in the individual, as I have said, the defect is unalterable; and if the difference between red and green is uncertain at eight years of age, it will be equally uncertain at eighty. Hence the existence of colour-blindness, among those who have to control the movements of ships or of railway trains, constitutes a real danger to the public; and it is highly important that the colour-blind, in their own interests as well as in those of others, should be excluded from employments the duties of which they are unfit to discharge.

The attempts hitherto made in this country to exclude the colour-blind from railway and marine employment have not been by any means successful. As far as the merchant navy is concerned, so-called examinations have been conducted by the Board of Trade, with results which can only be described as ludicrous. Candidates have been "plucked" in colour at one examination, and permitted to pass at a subsequent one; as if correc colour-vision were something which could be acquired Such candidates were either improperly rejected on the first occasion, or improperly accepted on the second. On English railways there has been no uniformity in the methods of testing; except, in so far as I am acquainted with them, that they have been almost uniformly misleading, calculated to lead to the imputation of colour-blindness where it did not exist, and to leave it undiscovered where it did. In these circumstances it is not surprising that great discontent should have arisen among railway men in relation to the subject; and this discontent has led, indirectly, to the appointment of a Committee by the Royal Society, with the sanction of the Board of Trade, for the purpose of investigating the whole question as completely as may be possible.

It is perhaps worth while, before proceeding to describe the manner in which the colour-sense of large bodies of men should be tested for industrial purposes, to say something as to the amount of danger which colour-blindness produces. A locomotive, as we all know, is under the charge of two men—the driver and the fireman. In a staff of one thousand of each, allotted to one thousand locomotives, we should expect, in the absence of any efficient method of examination, to find forty colour-blind drivers, and forty colour-blind firemen. The chances would be one in twenty-five that either the driver or the fireman on any particular engine would be colour-blind; they would be one in 625 that both would be colour-blind. These figures appear to show a greater risk of accident than we find realized in actual working, and it is manifest that there are compensations to be taken into account. In the first place, the term "colour-blind" is itself in some degree misleading; for it must be remembered that the signals to which the colour-blind person is said to be "blind" are not invisible to him. To the red-blind, the red light is a less luminous green; to the green-blind, the green light is a less luminous red. The danger arises because the apparent differences are not sufficiently characteristic to lead to certain and prompt identification in all states of illumination and of atmosphere. It must be admitted, therefore, that a colour-blind driver may be at work for a long time without mistakes; and it is probable, knowing as he must that the differences between different signal lights appear to him to be only trivial, that he will exercise extreme caution. Then it must be remembered that lights never appear to an engine-driver in unexpected places. Before being intrusted with a train, he is taken over the line, and is shown the precise position of every light. If a light did not appear where it was due, he would naturally ask his fireman to aid in the look-out. It must be also remembered that to overrun a danger signal does not of necessity imply a collision. A driver may overrun the signal, and after doing so may see a train or other obstruction on the line, and may stop in time to avoid an accident. In such a case, he would probably be reported and fined for overrunning the signal; and, if the same thing occurred again, he would be dismissed for his assumed carelessness, probably with no suspicion of his defect. Colour-blind firemen are unquestionably thus driven out of the service by the complaints of their drivers; and none but railway officials know how many cases of overrunning signals, followed by disputes as to what the signals actually were, occur in the course of a year's work. I have never heard of an instance in this country, in which, after a railway accident, the colour-vision of the driver concerned, or of his fireman, has been tested by an expert, on the part either of the Board of Trade or of the Company; but a fireman in the United States has recently recovered heavy damages from the Company for the loss of one of his legs in a collision which was proved to have been occasioned by the colour-blindness of the driver. Looking at the whole question, I feel that the danger on railways is a real one, but that it is minimized by the several considerations to which I have referred, and that it is much smaller than the frequency of the defect might lead us to think likely.

At sea, the danger is much more formidable. The lights appear at all sorts of times and places, and there may be only one responsible person on the look-out. Mr. Bickerton, of Liverpool, has lately published accounts of three cases in which the colour-blindness of officers of the mercantile marine, all of whom had passed the Board of Trade examination, was accidentally discovered by the captains being on deck when the officers in question gave wrong orders consequent upon mistaking the light shown by an approaching vessel. The loss of the *Ville du Havre* was almost certainly due to colour-blindness; and a very fatal collision in American waters, some years ago, between the *Isaac Bell* and the *Lumberman*, was traced, long after the event, to the colour-blindness of a pilot, who had been unjustly accused of being drunk at the time of the occurrence. In how many instances colour-blindness has been the unsuspected cause of wrecks and other calamities at sea, it is impossible to do more than conjecture.

It is necessary, then, alike in the public interest and in the interest of the colour-blind, who have doubtless often suffered in the misfortunes which their defects have produced, to detect them in time to prevent them from entering into the marine and railway services; and the next question is, how this detection should be accomplished. We have to distinguish the colour-blind from the colour-sighted; but we must be careful not to confound colour-blindness with the much more common condition of colour-ignorance.

It would surprise many people, more especially many ladies, to discover the extent to which sheer ignorance of colour prevails among boys and men of the labouring classes. Many, who can see colours perfectly, and who would never be in the least danger of mistaking a railway signal, are quite unable to name colours or to describe them; and they are sometimes unable to perceive, for want of education of a faculty which they notwithstanding possess, anything like fine shades of difference. Mr. Gladstone once published a paper on the scanty and uncertain colour-nomenclature of the Homeric poems; and he might have found very similar examples among his own contemporaries and in his own country. I have lately seen a pattern card of coloured silks, issued by a Lyons manufacturer, which contains samples of two

thousand different colours, each with its more or less appropriate name. There is here a larger colour-vocabulary than the entire vocabulary, for the expression of all his knowledge and of all his ideas, which is possessed by an average engine-driver or fireman; and, just as most of us would be ignorant of the names of the immense majority of the colours displayed on that card, so hundreds of men and boys among the labouring classes, especially in large towns, where the opportunities of education by the colours of flowers and insects are very limited, are ignorant of the names of colours which persons of ordinary cultivation mention constantly in their daily talk, and expect their children to pick up and to understand unconsciously. It is among people thus ignorant that the officials of the Board of Trade, and of railways, have been most successful in finding their supposed colour-blind persons; and these persons, who would never have been pronounced colour-blind by an expert, have been able, as soon as they have paid a little attention to the observation and naming of colour, to pass an official examination triumphantly. The sense of colour presents many analogies to that of hearing. Some people can hear a higher or a lower note than others, the difference depending upon structure, and being incapable of alteration. No one who cannot hear a note of a certain pitch can ever be trained to do so; but, within the original auditory limits of each individual, the sense of hearing may be greatly improved by cultivation. In like manner, a person who is blind to red or green must remain so; but one whose colour-sense is merely undeveloped by want of cultivation may have its acuteness for fine differences very considerably increased.

In order to test colour-vision for railway and marine purposes, the first suggestion which would occur to many people would be to employ as objects the flags and signal lanterns which are used in actual working. I have heard apparently sensible people use, with reference to such a procedure, the phrase upon which Faraday was wont to pour ridicule, and to say that the fitness of the suggested method "stands to reason." To be effectual, such a test must be applied in different states of atmosphere, with coloured glasses of various tints, with various degrees of illumination, and with the objects at various distances; so that much time would be required in order to exhaust all the conditions under which railway signals may present themselves. This being done, the examinee must be either right or wrong each time. He has always an even chance of being right; and it would be an insoluble problem to discover how many correct answers were due to accident, or how many incorrect ones might be attributed to nervousness or to confusion of names.

We must remember that what is required is to detect a colour-blind person against his will; and to ascertain, not whether he describes a given signal rightly or wrongly on a particular occasion, but whether he can safely be trusted to distinguish correctly between signals on all occasions. We want, in short, to ascertain the state of his colour-vision generally; and hence to infer his fitness or unfitness to discharge the duties of a particular occupation.

For the accomplishment of this object, we do not in the least want to know what the examinee calls colours, but only how he sees them, what colours appear to him to be alike and what appear to be unlike; and the only way of attaining this knowledge with certainty is to cause him to make matches between coloured objects, to put those together which appear to him to be essentially the same, and to separate those which appear to him to be essentially different. This principle of testing was first laid down by Seebeck, who required from examinees a complete arrangement of a large number of coloured objects; but it has been greatly simplified and improved by Prof. Holmgren, who pointed out that such a complete arrangement was superfluous, and that the only thing required was to cause the examinee to make matches to certain test colours, and, for this purpose, to select from a heap which contained not only such matches but also the colours which the colour-blind were liable to confuse with them.

After many trials, Holmgren finally selected skeins of Berlin wool as the material best suited for this purpose; and his set of wools comprises about 150 skeins. The advantages of his method over every other are that the wool is very cheap, very portable, and always to be obtained in every conceivable colour and shade. The skeins are not lustrous, so that light reflected from the surfaces does not interfere with the accuracy of the observation; and they are very easily picked up and manipulated, much more easily than coloured paper or coloured glass. The person to be tested is placed before a table in good daylight, the table is covered by a white cloth, and the skeins are thrown upon it in a loosely arranged heap. The examiner then selects a skein of pale green, much diluted with white, and throws it down by itself to the left of the heap. The examinee is directed to look at this pattern skein and at the heap, and to pick out from the latter, and to place beside the pattern, as many skeins as he can find which are of the same colour. He is not to be particular about lighter or darker shades, and is not to compare narrowly, or to rummage much amongst the heap, but to select by his eyes, and to use his hands chiefly to change the position of the selected material.

In such circumstances, a person with normal colour-sight will select the greens rapidly and without hesitation, will select nothing else, and will select with a certain readiness and confidence easily recognized by an experienced examiner, and which may even be carried to the extent of neglecting the minute accuracy which a person who distrusts his own colour-sight will frequently endeavour to display. Some normal-sighted people will complete their selection by taking greens which incline to yellow, and greens which incline to blue, while others will reject both; but this is a difference depending sometimes upon imperfect colour education, sometimes upon the interpretation placed upon the directions of the examiner, but the person who so selects sees the green element in the yellow-greens and in the blue-greens, and is not colour-blind. The completely colour-blind, whether to red or to green, will proceed with almost as much speed and confidence as the colour-sighted; and will rapidly pick out a number of drabs, fawns, stone-colours, pinks, or yellows. Between the foregoing classes, we meet with a few people who declare the imperfection of their colour-sense by the extreme care with which they select, by their slowness, by their hesitation, and by their desire to compare this or that skein with the pattern more narrowly than the conditions of the trial permit. They may or may not ultimately add one or more of the confusion colours to the green, but they have a manifest tendency to do so, and a general uncertainty in their choice. One of the great advantages of Holmgren's method over every other is the way in which the examiner is able to judge, not only by the final choice of matches, but also by the manner in which the choice is made, by the action of the hands, and by the gestures and general deportment of the examinee.

When confusion colours have been selected, or when an unnatural slowness and hesitation have been shown in selecting, the examinee must be regarded as either completely or incompletely colour-blind. In order to determine which, and also to which colour he is defective, he is subjected to the second test. For this, the wool is mixed again, and the pattern this time is a skein of light purple—that is, of a mixture of red and violet, much diluted with white. To match this, the colour-blind always selects deeper colours. If he puts only deeper purples, he is incompletely colour-blind. If he takes blue or violet, either with or without purple, he is completely red-blind. If he

takes green or gray, or one alone, with or without purple, he is completely green-blind. If he takes red or orange, with or without purple, he is violet-blind. If there be any doubt, the examinee may be subjected to a third test, which is not necessary for the satisfaction of an expert, but which sometimes strengthens the proof in the eyes of a bystander. The pattern for this third test is a skein of bright red, to be used in the same way as the green and the purple. The red-blind selects for this dark greens and browns, which are much darker than the pattern; while the green-blind selects greens and browns which are lighter than the pattern.

The method of examination thus described is, I believe, absolutely trustworthy. It requires no apparatus beyond the bundle of skeins of wool, no arrangements beyond a room with a good window, and a table with a white cloth. In examining large numbers of men, they may be admitted into the room fifty or so at a time, may all receive their instructions together, and may then make their selections one by one, all not yet examined watching the actions of those who come up in their turn, and thus learning how to proceed. The time required for large numbers averages about a minute a person. I have heard and read of instances of colour-blind people who had passed the wool test satisfactorily, and had afterwards been detected by other methods, but I confess that I do not believe in them. I do not believe that in such cases the wool test was applied properly, or in accordance with Holmgren's very precise instructions; and I know that it is often applied in a way which can lead to nothing but erroneous results. Railway foremen, for example, receive out of store a small collection of coloured wools selected on no principle, and they use it by pulling out a single thread, and by asking the examinee, "What colour do you call that?" Men of greater scientific pretensions than railway foremen have not always selected their pattern colours accurately, and have allowed those whom they examined, and passed, to make narrow comparisons between the skeins in all sorts of lights, in a way which should of itself have afforded sufficient evidence of defect.

Although, however, the expert may be fully satisfied by the wool test that the examinee is not capable of distinguishing with certainty between red and green flags or lights in all the circumstances in which they can be displayed, it may still remain for him to satisfy the employer who is not an expert, the railway manager, or the ship-owner, and to convince him that the colour-blind person is unfit for certain kinds of employment. It may be equally necessary to convince other workmen that the examinee has been fairly and rightly dealt with. Both these objects may be easily attained, by the use of slight modifications of the lights which are employed. Lanterns for this special purpose were contrived, some years ago, by Holmgren himself, and by the late Prof. Donders of Utrecht, and what are substantially their contrivances have been brought forward within the last few months as novelties, by gentleman in this country who have re-invented them. The principle of all is the same—namely, that light of varying intensity may be displayed through apertures of varying magnitude, and through coloured glass of varying tints, so as to imitate the appearances of signal lamps at different distances, and under different conditions of illumination, of weather, and of atmosphere. To the colour-blind, the difference between a red light and a green one is not a difference of colour, but of luminosity; the colour to which he is blind appearing the less luminous of the two. He may therefore be correct in his guess as to which of the two is exhibited on any given occasion, and he is by no means certain to mistake one for the other when they are exhibited in immediate succession. His liability to error is chiefly conspicuous when he sees one light only, and when the conditions which govern its luminosity depart in any degree from those to which he is most accustomed. With the lanterns of which I have spoken, it is always possible to deceive a colour-blind person by altering the luminosity of a light without altering its colour. This may be done by diminishing the light behind the glass, by increasing the thickness of the red or green glass, or by placing a piece of neutral tint, more or less dark, in front of either. The most incredulous employer may be convinced, by expedients of this kind, that the colour-blind are not to be relied upon for the safe control of ships or of locomotives. With regard to the whole question, there are many points of great interest, both physical and physiological, which are still more or less uncertain; but the practical elements have, I think, been well-nigh exhausted, and the means of securing safety are fully in the hands of those who choose to master and to employ them. The lanterns, in their various forms, are useful for the purpose of thoroughly exposing the colour-blind, and for bringing home the character of their incapacity to unskilled spectators; but they are both cumbrous and superfluous for the detection of the defect, which may be accomplished with far greater ease, and with equal certainty, by the wool test alone.

I have already mentioned that the examinations which have been conducted in the United States, thanks to the indefatigable labours of Dr. Joy Jeffries, have led to the discovery of an enormous and previously quite unsuspected amount of colour-ignorance, the condition which is frequently mistaken for colour-blindness by the methods of examination which are in favour with railway companies and with the Board of Trade; and this colour-ignorance has been justly regarded as a blot on the American system of national education. It has therefore, in some of the States, led to the adoption of systematic colour-teaching in the schools; and, for this purpose, Dr. Joy Jeffries has introduced a wall-chart and coloured cards. The children are taught, in the first instance, to match the colours in the chart with those of the cards distributed to them; and, when they are tolerably expert at matching, they are further taught the names of the colours. It must, nevertheless, always be remembered that a knowledge of names does not necessarily imply a knowledge of the things designated; and that colour-vision stands in no definite relation to colour-nomenclature. Even this system of teaching may leave a colour-blind pupil undetected.

COMPOUND LOCOMOTIVES.

THE present position of locomotive engineering in this country is of a very interesting nature; owing to the gradual increase of weight of trains hauled and the higher speeds now in use, it has been necessary to increase the power of the locomotive by leaps and bounds to cope with these demands. This naturally has not been done without great scheming on the part of the designers, for, with the standard gauge of railway of 4 feet 8½ inches, the engines are tied down to certain dimensions between the frame plates; in total length, to a certain extent, by the turntables in use; and in height of boiler for reasons of stability. These questions of design are interesting because they are intimately connected with the economical working of the engines, especially in the consumption of fuel, a question which of late years has taken a prominent position in the economical management of locomotives. For several years the highly economical results obtained at sea with the use of high pressures coupled with the compound or triple expansion engine have caused engineers to look in that direction for further improvements, with the result that two different types of compound locomotives were designed, and are considerably past the experimental stage. These engines are now working successfully on two of the English railways, and are being adopted on many foreign ones.

The type of compound locomotives first used in any number is that patented by Mr. F. W. Webb, the able Mechanical Superintendent of the London and North-Western Railway. This design is interesting because it is to a certain extent an example of really original work in locomotive practice. Mr. Webb had several very good ideas to work on in this design, all of very great importance from an engineer's point of view. These ideas were as follows:—The engine must not have a double-throw crank-axle, this being certainly the weak point of all inside-cylinder engines; the coupling rods between driving and trailing wheels must be done away with, since these also sometimes break, and may cause serious accidents. The doing away with the coupling rods enables a longer fire-box to be used, because the coupled wheels should be near together to obtain a minimum length of coupling rod, for reasons of safety. Thus, to design an engine to be more powerful than an ordinary four-coupled express of the North-Western heavy pattern, and having at the same time fewer parts liable to accident, as stated above, requires some clever scheming and much thought. The engine ultimately adopted by Mr. Webb for use on the London and North-Western Railway has three cylinders, viz. two high-pressure cylinders and one low-pressure cylinder. The high-pressure cylinders are placed one on each side of the engine, and are connected to the trailing or hind pair of wheels. The low-pressure cylinder is placed between the frames at the front end of the engine, and is connected with the front pair of driving wheels by a single-throw crank-axle. It will be noticed that in this arrangement each pair of wheels are driving wheels, that the side or coupling rods are done away with, and that the ordinary double-throw crank-axle has given place to a single-throw crank-axle, which may be made of ample dimensions and practically unbreakable. The course of the steam through the cylinders is easily understood: steam passes from the boiler to each high-pressure cylinder, and, after doing a certain amount of work, it is led from each high-pressure cylinder into the steam-chest of the low-pressure cylinder; it is there expanded down to a still lower pressure, and then exhausted finally up the chimney.

The cylinders of the *Dreadnought* type—that is, the most powerful type of the compounds on the London and North-Western Railway—are: high-pressure cylinders, 14 inches in diameter and 24 inches stroke; the low-pressure cylinder has a diameter of 30 inches and 24 inches stroke. These engines are designed in such a manner that, when working at their usual speed, the power developed by the high-pressure cylinders, and applied through the hind pair of wheels, shall be about equal to the power of the low-pressure cylinder, and applied to the front pair of driving wheels.

Through the kindness of Mr. Webb I am able to give an account of the working of a special train, run in order to test the fuel and water consumption of this class of engine.

On April 17, 1887, the engine *Dreadnought*, No. 503, worked a special train of coaches and dynamometer car from Crewe to Wolverton, a distance of 105¾ miles, at a speed of 24 miles per hour, including stoppages, which were made every 15 miles on the journey; 24 cwt. of coal were put into the fire-box during the trip, which gives a consumption of 25·4 lbs. of coal per mile; 2629 gallons of water were evaporated, which equals 9·78 lbs. of water per pound of coal consumed. The weight of the train, exclusive of engine and tender, was 259 tons, 3 cwts. 3 qrs, and the mean weight of engine and tender 62 tons 13 cwts., or a total of 321 tons 16 cwts. 3 qrs. for the whole train. This is equivalent to 4·13 tons of train hauled to 1 ton of engine and tender hauling it, and 1·26 oz. of coal per ton per mile.

The same locomotive worked a similar train between the same points on January 1, 1888, but at a speed of 44 miles per hour, with one stoppage only at Rugby, the results being as follows:—30 cwts. of coal were put into the fire-box during the trip, which gives a consumption of 41·3 lbs. of coal per mile; 3608 gallons of water were evaporated, which equals 8·26 lbs. of water per pound of coal consumed. The weight of the train, exclusive of engine and tender, was 256 tons, 18 cwts., and the mean weight of the engine and tender 62 tons 13 cwts., or a total of 319 tons 11 cwts. for the whole train. This is equivalent to 4·1 tons hauled to 1 ton of engine and tender hauling it, and 2·06 oz. of coal per ton per mile.

When the first trip was made, the weather was warm and dry, but during the latter a hard frost prevailed. With this exception the conditions under which the trips were made were practically alike. The difference in fuel consumption between the two trips may be taken as that due to the difference in speed. There are 77 compound locomotives now at work on the London and North-Western Railway, which have run to the end of December 1889 a total of 13,423,798 miles, and several more of the same type are now being built at Crewe Works.

It will be observed that in the Webb type of compound locomotive the design is such that the sizes of the cylinders can be easily increased if necessary to obtain a still more powerful engine, provided, of course, a larger boiler is used, and there is no reason why even the *Dreadnought* should not be the forerunner of still more powerful compounds on the London and North-Western Railway when their use becomes a necessity. It is evident that the use of a third cylinder, with motion and gear, must entail a greater cost for repairs as well as a larger consumption of oil when at work, and that the type of engine does not easily lend itself to a speedy and economical rebuild of ordinary locomotives to the Webb compound type; the system, therefore, is one quite unique in its way, and unlike any of the earlier attempts at compounding locomotives.

Another successful design of compound locomotives is that due to Mr. T. W. Worsdell, the Locomotive Engineer of the North-Eastern Railway, on which railway a large number of compound locomotives are at work. The Worsdell compound is the outcome of many experiments both at home and abroad. There are two cylinders used, and to all appearances the locomotives are similar to the ordinary non-compound locomotive. These two cylinders are of different diameters, and the steam, after doing work in the smaller one, is exhausted into the steam-chest of the larger or low-pressure cylinder, where it is further reduced in pressure by expansion in the cylinder, and afterwards is exhausted. It will be observed that in the Webb system there are two high-pressure cylinders connected to the hind pair of wheels, with the crank-pins, of course, at right angles, and that the low-pressure piston receives no steam from the high-pressure cylinders until the engine has commenced to move. Thus, all the work of starting the train for the first few revolutions of the driving wheels has to be done by the high-pressure pistons, and these are always able to start, in whatever position the wheels may be, because they are in duplicate and have no dead point. In the Worsdell system this is not possible without some special appliance, and it is this particular appliance which constitutes the patented device in the engine which makes it the success it is. In any two cylindered compound engine with cranks at right angles, which is the usual practice, it is possible to easily observe that there are two positions from which the engine cannot start on the admission of steam, because the admission of steam to the low-pressure cylinder depends on the exhaust from the high-pressure cylinder, and the high-pressure piston may happen to be at exactly the end of its stroke, either at the front or the back end—known as being on the centre or dead points. As the Worsdell engine is constructed with two cylinders, as before stated, it will be

interesting to know how the difficulty has been got over. When the high-pressure piston is at the end of its stroke, the low-pressure piston will be at the middle of its stroke, the cranks being at right angles; and if by any means steam could be admitted to the low-pressure cylinder without affecting the high-pressure piston, the engine would, of course, be able to turn round half a revolution, and so place the high-pressure piston immediately in a position to commence its stroke. The "intercepting valve," as it is called, is an arrangement by which the passage between the high- and low-pressure cylinders can be closed, and at the same time admits steam to the low-pressure cylinder when the high-pressure piston is on one or other of its dead points. This arrangement consists of a valve in the passage between the cylinders connected to a small piston in a cylinder placed in a suitable position. The steam supply is taken from the main steam-pipe, and regulated in its passage to the small cylinder by a valve worked from the foot-plate. If the engine refuses to start when the regulator is opened, the lever connected to the intercepting valve apparatus is pulled over. This admits steam behind the small piston, which immediately is forced forward and closes the intercepting valve, at the same time opening a port through which the steam is admitted to the low-pressure cylinder. This starts the engine, and the lever is returned to the running position by means of a spring. The rise of pressure in the passage between the cylinders, owing to the exhaust from the high-pressure cylinder, opens the intercepting valve, and compound working commences. This arrangement is very simple and trustworthy in practice. A large number of Worsdell compounds are now in use in India and elsewhere with admirable results. Where coal costs forty shillings and more per ton, it is very important that the most economical engine should be used.

On the Brighton Railway very economical results have long been obtained with the ordinary locomotives designed by the late Mr. Wm. Stroudley, and are due to the general excellence of design of boiler and engine, coupled with careful driving, induced by the coal premium. If locomotives were generally worked more by the reversing lever and less by the regulator, more economical results would be recorded; or, in other words, expansive working means economical working, which in the ordinany engine depends on the driver. In this manner, to work steam expansively in the non-compound locomotive, it is necessary for the driver to regulate the power of the engine by varying the quantity of steam used in the cylinders by means of an earlier or later cut-off, regulated by means of the reversing gear, the supply from the boiler not being checked in any way when running. On the other hand, the engine can be regulated by varying the steam supply at the regulator, the degree of expansion in this case being such as the driver chooses to generally use. Under the first conditions all the steam used is worked expansively, and under the latter the cylinders are choked with steam at one minute, and have an insufficient supply at the next. On the other hand, with the compound engine the steam must be expanded to a certain extent whether the driver likes it or not, and a result may be obtained with careless driving from the compound which would be passable when shown by a fairly well driven ordinary engine.

Mr. Drummond, the Locomotive Superintendent of the Caledonian Railway, has been making extensive experiments with steam-pressures varying from 150 to 200 lbs. per square inch, with identical engines doing practically the same work, the results of which will be given to the Institution of Civil Engineers. Without dealing with the practical difficulties involved in the use of such high pressures in non-compound locomotives, it will be highly interesting to know the results of these experiments. Whether the saving in fuel will equal or exceed the compound results obtained by Messrs. Webb and Worsdell is a moot point.

It has been observed that the saving of fuel due to a compound locomotive when working similar trains with the non-compound engine is due to the higher pressure used, and that when the pressure is reduced to the same level as that used in the non-compound engine the saving in fuel at once drops considerably, and the results give a little saving in favour of the compound. From this it is evident that to alter an ordinary engine to the compound system, without raising the working pressure, will be of little good, and not worth the cost.

The many statements made in order to prove the more economical working of the compound over the non-compound locomotive are misleading in the extreme, and as a fair comparison of the two types they are of no value. The compound locomotives have large boilers, ample heating surface, and all recent improvements, besides the all-important feature of a working pressure of 175 lbs. per square inch. This engine is compared with an ordinary non-compound locomotive having a smaller boiler, generally hard pressed for steam, because it has to haul its maximum load, with a working pressure of about 150 to 160 lbs. to the square inch. To put two such engines into competition is absurd, and therefore the results obtained by the compound locomotives in everyday working cannot fairly be compared with the non-compound engine's records.

For these and other reasons engineers are anxiously waiting to learn the results of Mr. Drummond's experiments, for then for the first time will it be possible to fairly compare the two systems.

It must not be imagined that because the compound and triple expansion marine engine is so successful in fuel economy, the compound locomotive is also likely to be so: the conditions of working are so totally different; for instance, the engines of an Atlantic liner work for seven or more days, doing practically the same amount of work the whole time, and since the work is constant the engines are designed to do that work in the most economical manner. With the locomotive, on the other hand, the work is never constant, and for that reason the steam supply is an ever-varying quantity, besides the constant stopping and reversing always going on when any shunting has to be done. These conditions are fatal to very economical working, and more especially when applied to a compound locomotive.

The compound principle is a sound one, but one not likely to be generally adopted, on account of extra complication. The present consumption of fuel by ordinary well-designed non-compound locomotives (take, for instance, the Brighton average consumption of 24·75 lbs. per mile for all their passenger engines) has not been beaten by the compound locomotive records; and until it can be demonstrated that a distinct economy is possible by their general use, they are not likely to increase largely in number.

N. J. L.

NEW ZOOLOGICAL PARK AT WASHINGTON.

By an Act of Congress passed on March 2 last year, an "appropriation" was made for the establishment of a Zoological Park in the district of Columbia "for the advancement of science and the instruction and recreation of the people." The control of the establishment was intrusted to a Commission composed of the Secretary of the Interior, the President of the Board of Commissioners of the District of Columbia, and the Secretary of the Smithsonian Institution.

Although the Commission was thus established only a year ago, the three Commissioners have already set to work, and, as we learn from their report, transmitted in January last to the Senate and House of Representatives

have accomplished the first object of the constitution—namely, the purchase of the necessary land.

The site selected for the Zoological Park is about two miles from the centre of Washington. It contains an area of 166 acres, traversed by the stream called Rock Creek, and is stated to possess most attractive features which render it well adapted for the purpose.

There is already a Zoological Garden at Philadelphia in good working order, and there is a smaller establishment at New York, in the Central Park, under the charge of Mr. W. A. Conklin, who is well known to many naturalists on this side of the Atlantic. The new institution at the metropolis of the United States, to be inaugurated and carried on by the Central Government for the "recreation and instruction" of the American people, will evidently be on a much larger scale. It will also have the advantage of the unlimited support always accorded by the Americans to their great national undertakings. If the Commissioners are inclined to take advice from Europe—and we have no reason to suppose the contrary—we should recommend that, before planning and commencing the necessary buildings, they should visit the Gardens of the Zoological Society in London, and the principal institutions of a like nature on the Continent, and take advantage of the experience gained by previous workers in the same field. No amount of plans and estimates, which, we are told, they are now asking for from the older institutions, will give them the advantages to be derived from a personal examination of these establishments and a few weeks' study of the mode in which they are worked.

JAMES NASMYTH.

EVERYONE was sorry to hear of the death of Mr James Nasmyth, the great engineer. His name is familiar to the entire English-speaking world, and there can be no doubt that he stands in the front rank of those who have advanced the material interests of mankind by the application of science to industrial methods.

So far as outward events were concerned, there was nothing very remarkable in his career. The real history of his life is the history of his inventions. He was born at Edinburgh on August 19, 1808, and was the youngest child of a family of eleven. His father was Alexander Nasmyth, who achieved considerable distinction as a painter. In a good summary of the facts of his life, printed in the *Times* of May 8, it is said that the boy gave very early evidence of a decided taste for mechanical pursuits. At school this taste was strengthened by intimacy with the son of an ironfounder, whose works young Nasmyth was never tired of visiting. He displayed so much aptitude for model-making that when he began to attend scientific classes at the University of Edinburgh he was able to pay his own fees by the sale of models of steam-engines, and other mechanical contrivances.

In 1829, Mr. Nasmyth came to London, and the two following years he spent in the service of Mr. Maudslay, the founder of the well-known firm of engineers. He then returned to Edinburgh, where he devoted himself for a short time to the construction of a set of engineering tools. With these tools, and a very small capital, he ventured to begin business on his own account in Manchester; and so many orders for work were received that new premises soon became necessary. He accordingly secured a plot of ground, 12 acres in extent, at Particroft, near Manchester; and this site he covered with the collection of workshops known as the Bridgewater Foundry. It was at this establishment that Mr. Nasmyth invented and perfected the mechanical tools with which his name is associated. The most important of them is the steam-hammer, the power and delicacy of which are universally known. It was invented in 1839, when he was still a young man. The *Times* says:—"The first idea of the hammer occurred to its inventor when he was asked by the Great Western Railway Company to construct a wrought-iron intermediate paddle shaft for a proposed ship called the *Great Britain*. Other firms had declined to undertake the construction of a shaft with a size and diameter never before attempted. The paddle shaft was never forged, as the screw was invented about this time. But meanwhile Nasmyth had invented a means of raising an enormous block of iron to a sufficient height and of regulating and directing its descent upon the anvil below."

Among Mr. Nasmyth's other inventions we may mention his "reversing direct-acting rolling mill."

In 1857, at the age of 48, he retired from business; and from that time he lived at Penshurst, where he found an outlet for his energies in the enthusiastic study of astronomy—a study which led to the publication of "The Moon considered as a Planet, a World, and a Satellite," written by him in conjunction with Dr. James Carpenter. Mr. Nasmyth wrote also "Remarks on Tools and Machinery," in Baker's "Elements of Mechanism" (1858). An autobiography, edited by Dr. Smiles, was published in 1883. He inherited to some extent his father's artistic faculty, and the exercise of his talent for drawing was a constant source of genuine pleasure.

Mr. Nasmyth used to say that he had never known what it was to be ill. For some time, however, his health was manifestly failing; and several weeks ago he came to town. He stayed at Bailey's Hotel, Gloucester Road; and there, in his eighty-second year, he died, on Wednesday, May 7.

NOTES.

MR. ALFRED GILBERT, A.R.A., has been commissioned to execute the Joule Memorial at Manchester.

PROF. W. K. SULLIVAN, President of the Cork Queen's College, and well known as a chemist, died on Monday at the College. He was 68 years of age, and had held the position of President since 1872, in succession to the late Sir Robert Kane.

IT is announced that Sir Frederick Mappin, M.P., has handed over to his co-trustees of the Sheffield Technical School £1000 for the purpose of founding two scholarships, each of the value of £15 per annum, in perpetuity.

THE Paris Academy of Sciences has offered a prize of 3000 francs for the best essay on the phenomena of fertilization in Phanerogams, especially in reference to the division and translation of the nucleus, and the relation between these phenomena and those which occur in the animal kingdom, to be sent in before June 1, 1891.

PROF. VON NORDENSKIÖLD lately announced to the Stockholm Academy of Sciences that a scientific expedition would start during the summer for Spitzbergen. Among the party will be his son, M. G. Nordenskiöld, and MM. Klinckowström and Bahaman. The expenses of the expedition will be defrayed by Baron Dickson and M. F. Beijer, the publisher.

THE ethnological collections made by Prof. Bastian during his journey through Russian Central Asia, have been brought to Berlin by the Professor's companion, Herr A. Dsirne. Prof. Bastian is at present at Madras.

DR. THORODDSEN, of Reikjavik, to whom the Linné Memorial Medal has been given by the Stockholm Academy of Sciences for his collection of fossil plants, has received 1200 kronen (£65) from Baron Dickson to enable him to investigate the Icelandic peninsula of Sneefieldness. Dr. Thoroddsen hopes soon to conclude his geological researches concerning this ancient Norse settlement.

Mr. T. G. Paterson, of Edinburgh, has sent to the *Daily News* the following information regarding what will be the most northerly telephone in Europe:—"My brother, Mr. Spence Paterson, H.M. Consul for Iceland, writes to me: 'It is proposed to put up a telephone line between Reikjavik and Havnefiord. The cost of apparatus and construction is reckoned under Kr. 30,000, and a small company is to raise the capital.'"

We learn from *Humboldt* that in connection with the tenth International Medical Congress, to be held this year in Berlin from August 4 to 9, there is to be an International Medico-Scientific Exhibition. The following kinds of objects will be exhibited: new or improved scientific instruments and apparatus for biological and especially medical purposes, including apparatus for photography and spectrum analysis so far as they are of service to medicine; new pharmaceutical and chemical stuffs and preparations; new or improved instruments for operative purposes of medicine, including electrotherapy; new plans and models of hospitals, convalescent homes, disinfection arrangements, baths, &c.; new arrangements for care of the sick, including means of transport, and baths for invalids; newest apparatus for hygienic purposes, &c. Communications (marked "Ausstellungsangelegenheit") should be sent to the office of the Congress, Dr. Lassar, Berlin, N.W., Karlstrasse 19.

The dinner given in honour of M. de Lacaze-Duthiers by the Club called *Scientia*, on April 30, seems to have been a great success. It took place in the Hôtel Continental. M. Charles Richet, who presided, delivered an eloquent speech on the achievements of the Club's guest—"that conqueror of the sea, and apostle of zoology"—calling attention especially to his services as the founder of the marine laboratories of Roscoff and Banyuls.

The *Kew Bulletin* for May opens with an interesting collection of facts relating to efforts which are being made to obtain commercial rubber from the "Abba" tree of West Africa. There are also sections on a mealy bug which has lately been very destructive to cultivated plants at Alexandria; on Mauritius hemp machines; on Siberian perennial flax; and on Liberian coffee.

The several Australian Governments have completed their arrangements with regard to the Mining Exhibition which is to be held this year at the Crystal Palace. According to the *Australian Mining Standard*, the best display will probably be made by New South Wales. Mr. Wilkinson, the Government Geologist, will visit England as the official representative of that colony; and the collections to which high honours were awarded at the New Zealand Exhibition will be sent to London.

The first number of "Records of the Australian Museum," edited by Dr. E. P. Ramsay, the Curator, has been issued. The editor explains that the rapid increase in the collections of the Museum, and the gradual acquisition of extensive series of new, or little known, forms from Australia, New Guinea, and the Pacific Islands, have "forcibly brought under the notice of the trustees the necessity of officially publishing the investigations of their scientific staff." Accordingly the "Records" will appear as an occasional periodical. Among the contents of the first number are a report on a zoological collection from the Solomon Islands, by E. P. Ramsay and J. D. Ogilby; a re-description of an Australian skink, by the same writers; a report of a collecting trip to Mount Kosciusko, by R. Helms; general notes made during a visit to Mount Sassafras, Shoalhaven district, by R. Etheridge, Jun., and J. A. Thorpe; and a report on a collecting trip to North-Eastern Queensland during April to September 1889, by E. J. Cairn and R. Grant.

The Aëronautical Society of Great Britain will hold a meeting at the Society of Arts, on Friday, May 16, when a lecture will be delivered by Mr. Henry Middleton, of Slough, on "the fundamental principles of flight, and their application to the construction of flying machines." Mr. Edgar Stuart Bruce will read a short paper on electric balloon signalling, with details of some late experiments in Belgium.

An obituary notice of Theodor Kirsch has been issued as the fifth of the series of "Abhandlungen und Berichte" of the Dresden Zoological and Anthropological Museum, edited by Dr. A. B. Meyer. Herr Kirsch had charge of the entomological department of the Museum. The notice is accompanied by a portrait, and by a list of his writings.

The buildings of the Botanical Museum and Laboratory of the Michigan Agricultural College have been entirely destroyed by fire, and with them the whole of the Wheeler Herbarium, containing over 7000 species, the most complete collection of Michigan plants ever brought together.

The well-known botanical explorer Mr. C. C. Parry died at Davenport, Iowa, on February 20, from an illness following on an attack of influenza.

Dr. Tschirch, of Berlin, has been appointed Professor of Pharmacology in the University of Berne.

Dr. Istvánffy-Schaarschmidt has been appointed Curator of the botanical collections in the National Museum of Buda-Pesth.

Herr J. Bornmüller was engaged during April in a botanical investigation in Asia Minor. He began with the mountainous region in the neighbourhood of Amasia, and proceeded westwards into Galatia and Paphlagonia.

Two slight shocks of earthquake were felt at Sofia on May 10, at half-past 2 and at 3 o'clock in the afternoon. The seismic disturbances travelled in a vertical direction.

The Deutsche Seewarte has just published Part III. of "Ueberseeische meteorologische Beobachtungen," containing a valuable series of observations from distant stations, carefully compiled in the most desirable form. Full particulars are given about the positions of the stations, and the construction of the instruments.

We have received the Report of the Meteorological Service of the Dominion of Canada for the year 1886. It contains, as before, very clear tables of the daily, monthly, and quarterly means, for a large number of stations, and values of bright sunshine for 14 stations. The storm signal service seems to be much appreciated, and to be very successful; Mr. Carpmael states that, whenever a storm of any magnitude occurred, due warning was given to the shipping. The issue of daily weather forecasts has also been very successful—88·6 per cent. having been fully verified. The system of disseminating weather information, by attaching metal disks to the railway cars, has been perfected, and Mr. Carpmael states that these forecasts are as eagerly sought for by farmers and people resident in country districts as by the inhabitants of the towns where they are published. The Report also contains five coloured plates, showing the quarterly and annual distribution of rainfall in Ontario.

The daily and yearly variation, and the distribution, of wind-velocities in the Russian Empire have been fully investigated by Kiersnowski (*Repert. f. Meteor.*). The highest velocities (mean 6·3 metres per second) occur in the Baltic provinces. On the White Sea, on the Caspian, in the region of the North Russian lakes, and on the Steppe, the values are also high; in the forest region and the Caucasus they are low. Towards the interior of Asia the velocity decreases, and in Transbaikalia is the mini-

mum (1·5 m. per second). Further east, towards the Pacific, the velocity increases. In the annual period, the maximum is pretty uniformly in winter, the minimum in summer. A maximum in spring, and a minimum in summer or autumn, are peculiar to the Caspian region, the Ural, and West Siberia, with Central Asia. In Eastern Siberia the minimum is in winter. The daily variation shows distinctly the connection with cloudiness. The greatest amplitude occurs in the brighter part of the year; in East Siberia in winter, and in the rest of the country in summer. In general the amplitude increases regularly with the clearness of the sky eastward, and on land it is greater than on the sea.

A STATISTICAL investigation of lightning-strokes in Central Germany, covering a period of 26 years, has been recently carried out by Herr Kastner (*Globus*). The number of cases has increased about 129 per cent., and last year (1889) it amounted to 1145. The author distinguishes four thunderstorm paths. The starting-points of all these are in hills, and in their course, the woodless districts and flat country, river-valleys and low meadow-ground about lakes, seem specially liable, while the wooded and hilly parts generally escape. The hottest months (June, and especially July) and the hottest hours of the day, or those immediately following them (3 to 4 p.m.), show the most lightning strokes.

IN *Le Globe* for March, M. E. Chaix has an article on the general circulation of the ocean. He enters into the various means adopted for determining ocean currents, and the history of the various theories from the earliest times, and gives a brief summary of those which are now generally adopted. The author adopts the opinion expressed by Humboldt, that several causes must be sought for, and that they cannot be explained by any single one. His conclusions are: (1) that differences of density, especially those caused by temperature, induce a slow progression of the water at a depth towards the equator, but that their action is apparently nothing at the surface; (2) that the prevailing winds cause sensible currents at the surface, and these movements in time penetrate to a certain depth, but that their agency does not explain everything; (3) every motion, whether on the surface or at a depth, causes a compensating movement, either slow or rapid. These movements play the second part in the superficial circulation, and explain generally what cannot be attributed to the direct action of the wind; therefore they afford a key to a number of apparent anomalies.

IN the last report of the Central Park Menagerie, New York, it is noted that the principal cause of death among the animals in 1889 was congestion of the lungs. Among the most valuable specimens lost by this disease were—a lioness, purchased March 4, 1886; two pumas, one received in 1883, the other in 1885; one llama and one emu, both purchased in 1888; one sea-eagle and one migratory pigeon, the former of which had been in the collection for eighteen, the latter for thirteen, years. The death of a young hippopotamus, four days after birth, was also attributed to congestion of the lungs. In describing what happened in the case of this interesting creature, Mr. W. A. Conklin, the Director, points out that the Zoological Gardens of Europe have been particularly unfortunate in regard to the first-born of the hippopotamus. "The first two born in the London Garden lived two and four days respectively. The first two born in the Jardin des Plantes, Paris, were killed by their parents shortly after birth. In the Amsterdam Garden the first two died from the neglect of their parents, and in St. Petersburg Garden the first three died from the same cause."

IN a note in the current number of the *American Naturalist*, Mr. F. F. Payne, of Toronto, records an interesting fact which often came under his notice during a prolonged stay at Hudson's Strait. "Here," he says, "the Eskimo might often be seen lying at full length at the edge of an ice-floe, and, although no seals could be seen, they persistently whistled in a low note similar to that often used in calling tame pigeons, or, if words can express my meaning, like a plaintive phe-ew, few-few, the first note being prolonged at least three seconds. If there were any seals within hearing distance they were invariably attracted to the spot, and it was amusing to see them lifting themselves as high as possible out of the water, and slowly shaking their heads, as though highly delighted with the music. Here they would remain for some time, until one perhaps more venturesome than the rest, would come within striking distance of the Eskimo, who, starting to his feet with gun or harpoon, would often change the seal's tune of joy to one of sorrow, the others making off as fast as possible. The whistling had to be continuous, and was more effective if performed by another Eskimo a short distance back from the one lying motionless at the edge of the ice. I may add that the experiment was often tried by myself with the same result."

A NEW instalment of the "Palæontologia Indica" has been published. It forms the first part of vol. iv. of the series dealing with "salt-range fossils," by Dr. William Waagen. This volume is being written in fulfilment of a promise made by Dr. Waagen when, in 1879, he began his publications on the different rock-groups of the salt-range and the fossils contained therein. He then undertook to collect in a special volume "all the geological conclusions that may be drawn from the detailed study of the different faunæ, and to give at the same time geological details as to the occurrence of the single forms."

THE Straits Branch of the Royal Asiatic Society, has published the twentieth number of its Journal. It contains a report on the destruction of coco-nut palms by beetles, by H. N. Ridley; British Borneo—sketches of Brunai, Sarawak, Labuan, and North Borneo, by W. H. Treacher; notes on names of places in the island of Singapore and its vicinity, by H. T. Haughton; journal of a trip to Pahang, &c., by W. Davison; and a list of the birds of the Bornean group of islands, by A. H. Everett. A map of Borneo, and a map of Palawan and adjacent islands, are given. The former shows roughly the distribution of highlands and lowlands in Borneo, and the localities at which collections of birds have been made are indicated.

CLOSE to the Hungarian village of Toszeg, on low ground often flooded by the Theiss, are the remains of a prehistoric settlement, which have been recently described by a Scandinavian man of science, M. Undset. While in Upper Italy a sort of basin seems often to have been made with an earth-wall, and dwellings built in this on a pile-supported platform; the buildings near Tozseg have been similarly raised in two long parallel trenches. The hollow space under the platform served as a place for refuse of all sorts, and it must often have held stagnant water. When it got full, the settlement appears to have been burnt down, and a new set of buildings raised on new and higher piles. Among the remains are bones of cattle, stags, goats, swine, &c., vessels made of horn, stone, baked clay, a few bronze articles (needles, knives), polished stone hammers, wedges, chisels, tooth-ornaments, &c. The settlers seem to have practised agriculture, hunting, and fishing. Discussing this "find," M. Undset has some remarks on the relations of the prehistoric civilization of Hungary to that of Upper Italy and other European regions. In Northern Italy the bronze period proper appears to have corresponded pretty nearly with the *terramare* settlements; but in Hungary it was much longer, and was in great part contemporaneous with the iron period in Italy. When the bronze period began in Hungary is very doubtful, but M. Undset considers it to have been not later than in Upper Italy. It is highly probable that the very early migration of Italians into the Apennine peninsula, and the migrations into the Balkan

peninsula culminating in that of the Dorians, came from the middle or lower Danube valley. Hence the importance of prehistoric remains in Hungary for a knowledge of prehistoric events in Central Europe.

Another important paper is contributed by M. Moissan to the current number of the *Comptes rendus* upon carbon tetrafluoride, CF_4. Five modes of preparing the gas are described, together with several new properties which have been investigated since the publication of the preliminary notice a few weeks ago. When gaseous fluorine is allowed to enter a platinum tube filled with marsh gas, CH_4, a violent combination, accompanied by incandescence, takes place, carbon being deposited and a mixture of various fluorides including carbon tetrafluoride formed. Fluorine also reacts somewhat violently with chloroform, $CHCl_3$. When the free element is led into cooled chloroform it is largely absorbed, carbon tetrafluoride being again produced, and for the most part remaining dissolved in the excess of chloroform. If the fluorine is heated to 100° before passing into the chloroform incandescence occurs, a flame appears at the exit opening of the platinum apparatus, carbon is again deposited, and the tetrafluoride largely found in the gaseous product. Fluorine also expels chlorine from tetrachloride of carbon, CCl_4, for if it is led into a quantity of the tetrachloride contained in a gently-warmed platinum flask, the issuing gas is found to be a mixture of free chlorine and carbon tetrafluoride. A large proportion of the latter gas remains dissolved in the excess of carbon tetrachloride, and may be readily obtained fairly pure by gently boiling the residual liquid in a glass vessel and collecting the gas over mercury. As described in our notice of the preliminary paper the lighter varieties of amorphous carbon, such as wood charcoal and lamp black, take fire in a stream of fluorine and continue burning as long as combination occurs, the product consisting of several gaseous fluorides, of which the tetrachloride is present in greatest proportion. The method, however, by which carbon tetrafluoride can be prepared most conveniently and in the purest form is as follows. A quantity of silver fluoride, AgF, is placed in a brass U-tube fitted with two side tubes. Through one of these latter a stream of vapour of carbon tetrachloride is driven; the other serves as exit tube for the products of the reaction. The apparatus is first filled with carbon tetrachloride vapour, the portion containing the fluoride of silver is then heated to 195°–220° C. and a steady stream of the tetrachloride maintained as long as gas is evolved at the mercury trough. It is advisable to add to the apparatus a small metallic spiral tube which can be cooled to − 23° in order to condense any escaping vapour of the tetrachloride, and which is so arranged that the condensed liquid can be returned to the vessel in which the tetrachloride is being vapourized and so passed again into the reaction tube. The last traces of carbon tetrachloride may be removed by allowing the gas to stand twenty-four hours over mercury in contact with a few scraps of caoutchouc. In order to free it from admixed heavier fluorides advantage is taken of the fact that large quantities of the tetrafluoride are absorbed by absolute alcohol. On agitation with a little absolute alcohol, therefore, the tetrafluoride is absorbed, and may be again liberated either by addition of water, in which the gas is scarcely perceptibly soluble, or by ebullition. If the latter plan is adopted the alcohol vapour may be removed by washing through sulphuric acid. It is important to use a metallic reaction tube in the preparation, inasmuch as glass is rapidly attacked by carbon tetrafluoride, the product of the reaction in a glass vessel consisting of a mixture of silicon and carbon tetrafluorides, carbon dioxide, and a heavier fluoride of carbon, $CF_4 + SiO_2 = CO_2 + SiF_4$. Carbon tetrafluoride liquefies at − 15° at the ordinary atmospheric pressure, and under a pressure of four atmospheres at 20°. When passed over heated sodium it is completely absorbed, carbon being deposited and sodium-fluoride formed. Aqueous potash appears to be without action upon it, but alcoholic potash slowly absorbs it with formation of carbonate and fluoride of potassium.

The additions to the Zoological Society's Gardens during the past week include a Blossom-headed Parrakeet (*Palæornis cyanocephalus* ♂), two Red-eared Bulbuls (*Pycnonotus jocosus*) two Red-vented Bulbuls (*Pycnonotus hæmorrhous*), a Large Hill-Mynah (*Gracula intermedia*) from India, a Red-sided Eclectus (*Eclectus pectoralis* ♀) from New Guinea; two King Parrakeets (*Aprosmictus scapulatus* ♂ ♀), a Pennant's Parrakeet (*Platycercus pennanti*), a Chestnut-eared Finch (*Amadina castanotis* ♀) from Australia, a Ceylonese Hanging Parrakeet (*Loriculus asiaticus*) from Ceylon, a Mealy Amazon (*Chrysotis farinosa*), two Yellow-shouldered Amazons (*Chrysotis ochroptera*), a Blue-fronted Amazon (*Chrysotis æstiva*), a Red-crested Cardinal (*Paroaria cucullata*) from South America, a Levaillant's Amazon (*Chrysotis levaillanti*) from Mexico, two Panama Amazons (*Chrysotis panamensis*) from Panama, a Yellow-vented Bulbul (*Pycnonotus crocorrhous*) from Sumatra, two Orange-cheeked Waxbills (*Estrelda melpoda*), two Red-bellied Waxbills (*Estrelda rubriventris*), a Cut-throat Finch (*Amadina fasciata* ♂), a Shining Weaver Bird (*Hypochera nitens*), an Olive Weaver Bird (*Hyphantornis olivaceus*) from South Africa, a Crimson-crowned Weaver Bird (*Euplectes flammiceps*), a Grenadier Weaver Bird (*Euplectes oryx*), a Green Glossy Starling (*Lamprocolius chalybeus*) from West Africa, two Madagascar Weaver Birds (*Foudia madagascariensis* ♂ ♀) from Madagascar, a Red-headed Cardinal (*Paroaria larvata*) from Brazil, a Cardinal Grosbeak (*Cardinalis virginianus* ♀) from North America, presented by Dr. Seton; a Red-eared Bulbul (*Pycnonotus jocosus*), a Red-vented Bulbul (*Pycnonotus hæmorrhous*) from India, presented by Lieut.-General Sir H. B. Lumsden, K.C.S.I.; a Ring-necked Parrakeet (*Palæornis torquatus* ♀) from India, presented by Mrs. O. Harvey; a Redwing (*Turdus iliacus*), British, presented by Mr. J. Newton Hayley; a Common Viper (*Vipera berus*), a Slowworm (*Anguis fragilis*), British, presented by Dr. W. K. Sibley; three Green Tree Frogs (*Hyla arborea*) from France, presented by Mrs. Humphreys; two Hartebeests (*Alcelaphus caama* ♂ ♀) from South Africa, a Bennett's Wallaby (*Halmaturus bennetti* ♂) from Tasmania, a Black Wallaby (*Halmaturus walabatus* ♀), two Brush-tailed Kangaroos (*Petrogale penicillata* ♂ ♂) from New South Wales, four Common Quails (*Coturnix communis*), European, deposited; two Demoiselle Cranes (*Grus virgo*) from North Africa, purchased; a Japanese Deer (*Cervus sika* ♂), a Hog Deer (*Cervus porcinus* ♀), ten Cuming's Octodons (*Octodon cumingi*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

Objects for the Spectroscope.

Sidereal Time at Greenwich at 10 p.m. on May 15 13h. 34m. 18s.

Name.	Mag.	Colour.	R.A. 1890.	Decl. 1890.
			h. m. s.	° ′
(1) Uranus, May 15		Bluish-green.	13 27 40	− 8 33

(6) T Ursæ Maj	Var.	Red-yellow.	12 31 23	+ 60 6

Remarks.

(1) A question of great interest was raised last year by spectroscopic observations of the planet Uranus. As is well known, the spectra of Uranus and Neptune differ very widely from those of the other planets. They show no solar lines in the visible spectrum even when telescopes of very large apertures are em-

ployed; but in place of them there are several broad dark bands to which no origins have yet been assigned. Secchi first observed the spectrum in 1869, and he pointed out that, if the luminosity of the planet be due to solar light, it must undergo great modifications in the atmosphere of the planet. Vogel and Huggins re-observed the spectrum and mapped it in considerable detail, Vogel giving the positions of no less than twelve bands. The five principal bands have the following positions:—

618. Darkest part of a broad band, ill-defined towards the red.
596. Middle of a faint narrow band.
573·8. Darkest part of a broad band.
542·5. Middle of darkest band in spectrum.
486·1. Middle of a dark band.

It has not yet been possible to explain any of the dark bands by comparisons with known absorption spectra; one band is certainly coincident with the F line of the solar spectrum, but it is much too broad to be due to reflected sunlight. Prof. Lockyer gave his attention to the spectrum last year, and thought it possible that many of the apparent dark bands were simply contrast appearances due to the presence of radiation flutings. At his suggestion I examined the spectrum, and came to the conclusion that he was right. I afterwards made observations, in conjunction with Mr. Taylor, with Mr. Common's 5-foot reflector. A full account of the results is given in Mr. Taylor's paper on the subject (*Monthly Notices*, vol. xlix. p. 405). We decided in favour of bright flutings, and Mr. Taylor afterwards mapped them very carefully. The brightest fluting is near *b*, and it is remarkable that Secchi noted this brightening in his light-curve of the spectrum. Mr. Espin has since observed that the blue end of the spectrum is broken up into bright bands and dull shadings. If the apparent bright flutings are not contrast effects, as has been suggested, the planet must be to a great extent self-luminous. Dr. Huggins has since photographed the violet end of the spectrum, and finds nothing but solar lines—a fact which is very difficult to explain, when the remarkable character of the visible spectrum is considered.

It is highly important that further observations, by as many different observers as possible, should be made. The apparent diameter of the planet is so small that a Maclean spectroscope shows the bands very well, but the brightnesses are best seen when the spectrum is narrow, as is the case with bright-line stars.

(2) This nebula is thus described in the General Catalogue: "Bright; large; extended in a direction 150°; pretty suddenly brighter in the middle to a resolvable nucleus." The apparent size of the nebula, according to the Harvard College observations, is $3' \times 1'$. The spectrum has not been recorded.

(3) This star is one of considerable interest. Dunér says: "It appears to have a narrow band in the red, and a wide one in the green. Perhaps III.*a* (Group II.), but by no means III.*b* (Group VI.)." It has been suggested, from a discussion of the other members of the group, that the star is a representative of the very earliest stage of Group II., but further details are necessary before it can be said with certainty. The condition here should be almost cometary, and hence, in further observations, the bright flutings of carbon should be particularly looked for. So far, this is the only observed star which may possibly belong to the first species of the group.

(4 and 5) These stars are included in Vogel's spectroscopic catalogue. The first is stated to be of the solar type, and the second of Group IV. The usual observations are required in each case.

(6) This variable will reach a maximum about May 20. The range is from 6·4–8·5 to 13 in 255·6 days. The spectrum is one of Group II. (Dunér), the bands being wide, but not very dark. The usual observations for bright lines and other variations are suggested. A. Fowler.

Changes in the Magnitudes of Stars.—At the April meeting of the Royal Astronomical Society Mr. Isaac Roberts presented a photograph of stars in the regions of Tycho Brahe's Nova taken on January 12, with an exposure of 2 hours 55 minutes. D'Arrest charted the stars in the region of the Nova in 1864 down to the 16th magnitude, and this chart has been used by Mr. Roberts to compare with his photograph. He finds no appearance of either a nebula or of a star on the photograph in or about the position indicated by D'Arrest, but a comparison of the chart and catalogue with the photograph shows that changes have taken place both in the positions and magnitudes of several of the stars since 1864. The changes particularized are important when it is considered that they apply to less than half a degree in right ascension, and one degree in declination. That six of the stars shown on D'Arrest's chart and not shown on the photograph, are absent on the latter on account of some physical change having taken place in the stars, receives confirmation from the fact that the photograph shows more than 400 stars on a sky space where D'Arrest has charted only 212 stars.

A Mechanical Theory of the Solar Corona.—Prof. Schaeberle of the Lick Observatory, has propounded an entirely novel theory of the solar corona, a discussion of which will appear in the report of the eclipse of December 22, 1889. His investigations seem to prove that the corona is caused by light emitted and reflected from streams of matter ejected from the sun by forces which in general act along lines normal to the surface. These forces are most active near the centre of each sun-spot zone. Owing to the change of the position of the observer with reference to the plane of the sun's equator, the perspective overlapping and interlacing of the two sets of streamers at these zones causes the observed apparent change in the type of the corona. To roughly test the theory Prof. Schaeberle has stuck a lot of needles in a ball to represent the streams of matter, placed the model in a beam of parallel rays, and allowed its shadow to fall upon a screen, the result being that an infinite variety of forms similar to the coronal structure can be reproduced by simply revolving the model. It remains to be proved whether a comparison of the forms that are seen according as the observer is above, below, or in the plane of the sun's equator, agree with those that should be seen on this theory.

THE IRON AND STEEL INSTITUTE.

THE annual meeting of the Iron and Steel Institute was held on Wednesday and Thursday of last week, in the theatre of the Institution of Civil Engineers, the President, Sir James Kitson, occupying the chair. There was a fair programme of ten papers, and another was added after the list had been printed. The following were the papers read:—

On a new form of Siemens furnace, arranged to recover waste gases as well as waste heat, by Mr. John Head, London, and M. P. Pouff, Nevers.

Calculations concerning the possibility of regenerating the gas in the new Siemens furnace, by Prof. Åkerman, Stockholm.

On the critical points of iron and steel, by M. F. Osmond, Paris.

On the carburization of iron by the diamond, by Prof. W. C. Roberts-Austen, London.

The changes in iron produced by thermal treatment, by Dr. E. J. Ball, London.

On the Robert-Bessemer steel process, by Mr. F. Lynwood Garrison, Philadelphia.

Aluminium in carburetted iron, by Mr. W. J. Keep, Detroit.

On certain chemical phenomena in the manufacture of steel, by Mr. W. Galbraith, Chesterfield.

The estimation of phosphorus in the basic Siemens steel bath, by Mr. W. Galbraith, Chesterfield.

On the Rollet process for producing purified castings, by Mr. A. Rollet, St. Etienne.

The first six of these papers were read and discussed at the first day's sitting (Wednesday); and the remaining four were disposed of before lunch-time on Thursday. It is seldom that we have seen papers "rattled off"—the phrase most aptly describes the procedure—in so rapid a manner. The members who were present may certainly be congratulated upon having got through a great many papers in a very short space of time; but it is a question whether there would not have been a gain to knowledge had the discussions been of a somewhat more deliberate nature.

In addition to the above papers there was on the agenda a memoir by Sir Henry Roscoe, on the action of aluminium on iron and steel. This, however, was not forthcoming; a fact which is to be regretted, as also is the cause which led to it, the subject being one of considerable scientific and industrial importance at the present time, when the production of aluminium is being so much cheapened, and such great things are promised by those who advocate its use in the metallurgy of iron and steel. Fortunately Mr. Keep's paper was forthcoming, and this elicited a brief but useful discussion, in the course of which Mr. James Riley, of the Steel Company of

Scotland, and others, gave the valuable information drawn from the practical experience they had gained in the alloying of iron with aluminium on a large scale. We will, however, take the papers so far as space will permit, in the order in which they were read.

Mr. Head's paper was read at the Paris meeting of the Institute, held last autumn, but was not then discussed. The author first points out that, in 1817, the Rev. Robert Stirling and his brother James Stirling applied the regenerative principle to air-engines, and that both they and J. Slater, in 1837, and R. Laming in 1847, foresaw the possibility of its application to metallurgical operations. The new Siemens furnace, which was the subject of the paper, was described and illustrated by wall-diagrams, without reproducing which it is not possible to make the arrangement clear. The chief point is that the waste gases are reconverted into combustible gases by being taken partly through an air-regenerator, and partly under the grate of the producer, so that they distil the hydrocarbons from the coal; in fact, the gas-producer utilizes the heat formerly deposited in the air regenerators. A steam jet is used for starting the action. This new form of regenerative gas-furnace has been applied to the heating and welding of iron. It is to be used for puddling, and for copper and steel melting. It is claimed that it effects a saving in fuel of about two-thirds the weight, a reduction in the weight of iron equal to 5 per cent., and a saving in labour and repairs. Figures were quoted supporting these claims.

Prof. Åkerman's paper was a discussion on the theory of combustion raised by the process. The subject is one of considerable interest, and is well put forward by the author. His conclusions are of considerable interest from a philosophical point of view, but are to a great extent robbed of their importance from an operative standpoint, from the uncertainty existing upon the specific heat of gases at high temperatures; which is only one more fact emphasizing the want of a proved and trustworthy pyrometer.

A brief discussion followed, in which Sir Lowthian Bell took the chief part.

M. Osmond's paper was one of those which must be the despair of the writers of brief notices such as this. It consisted of 33 pages, giving results of experiments made to ascertain the effects of varying temperature on different alloys of iron. In the presence of such a mass of matter as this we can only refer our readers to the Transactions of the Institute, where they will find the facts detailed and the diagrams by which they were illustrated fully set forth. We will content ourselves with simply stating that the "critical points" are points of arrestation in the cooling of iron and steel. It is interesting to notice the effect of various alloys on this phenomenon. Perhaps, to those members who were not previously acquainted with the instrument, the description of the thermo-electric pyrometer of Le Chatelier was not the least interesting part of the paper. A valuable bibliography is given in an appendix. In the discussion Mr. Wrightson gave some particulars of experiments he had made to ascertain the change of volume of iron at different temperatures, which he did by plunging an iron ball into liquid iron. The ball would at first sink, but rise as it acquired heat, and indications were thus obtained, which appeared to correspond with the "critical points" of the author. Mr. Hadfield also made some interesting remarks on the state of carbon in iron.

Prof. Roberts-Austen's paper followed. The Professor is not, of course, the first to carburize iron by means of the diamond; indeed, it has been a somewhat favourite experiment, with which the name of more than one eminent physicist in times past has been associated. But Prof. Roberts-Austen is, we believe, the first to perform the operation *in vacuo*, the iron itself being previously heated *in vacuo* to deprive it of its occluded gas. The author of the paper refers to the experiments of Hempel, who heated diamond and iron in an atmosphere of nitrogen perfectly free from oxygen, and points out that his, the author's, experiments are interesting from the assertions made by a certain school of chemists that no two elements can react on each other unless a third be present. "It would appear, however," Prof. Roberts-Austen says, "that a mere 'trace' of such additional element is sufficient to insure combination; for, in the experiments I have described, carbon and iron in their purest obtainable forms were used, and the only additional matter which could have been present was the trace of occluded gas which the iron may possibly have retained." The author is satisfied that combination does not take place until a full red heat is reached.

Dr. Ball's paper dealt with the changes in the magnetic capacity and tensile strength of steel which occur at definite temperatures, and showed how these changes may be made evident when the metal is rapidly cooled in water or in oil. Two samples of steel, one basic Bessemer and the other acid open-hearth, were submitted. Analysis showed that all the elements for which tests are usually made were almost identical, except manganese, of which the percentages were 0·284 for Bessemer, and 0·546 for open-hearth. The results are plotted on three sets of diagrams, one diagram in each set showing the results obtained with tests hardened, from varying temperatures, in water, in oil, and annealed respectively; the sets of diagrams refer to unstrained bars, the same bars strained to the yield point, and the same bars strained almost to the breaking point. These last two papers were discussed together.

Mr. Garrison's paper was read at the Paris meeting of September last, but not then discussed. It describes an elliptical converter in which the *tuyères* are so arranged that they blow air at the surface of the metal in a manner which causes a rotary motion of the bath, combustion taking place at the surface. The device is not altogether new, as surface blowing was suggested, and, indeed, patented, by Sir Henry Bessemer in the early days of the Bessemer process.

Mr. Keep's paper on aluminium, in carburetted iron, was the first taken on the Thursday morning. In it the results of certain tests were given, the details being set forth in graphic form. The points noted were strength to resist both weight and impact, deflection, set, elasticity for stresses applied, shrinkage for cast metals, hardness, and rigidity. This paper must be read with others that have been brought forward by the author, whose work in connection with the subject is well known. As a general result the tests go to show that the effect of a proper quantity of aluminium on commercially pure iron is to produce a material which is soft, easily bent, and flows readily. Aluminium diminishes deflection by decreasing the set and elasticity. Rigidity is also increased, the grain is closer and more uniform; in short, the author claims that by aluminium the metal is improved in every way when considered as a structural material.

In the discussion which followed the reading of the paper, Mr. James Riley, the manager of the Steel Company of Scotland, said that he had tried the effect of aluminium in steel on a large scale, but had been disappointed in the results. There were advantages, but these were so slight as to be insufficient to pay for the additional expense of one to two pounds a ton. Fluidity was gained, tensile strength was very slightly increased, the elastic limit was raised considerably, and ductility was increased. If aluminium could be reduced sufficiently in price it would be good to use it, but Mr. Riley had not considered the game worth the candle, and had ceased to use it a year ago. He had, however, been induced lately, by being told of the wonderful results obtained, to make further experiments, but his present frame of mind was not to use aluminium excepting for very fine thin castings. Mr. Spencer, of Newburn, another large steel-maker who has achieved great success in certain special branches of manufacture, endorsed what Mr. Riley had said. Mr. Allen pointed out that there might be traces of aluminium in pig-iron without its being discovered, as chemists only tried, as a rule, for the usual alloys. It was also important to remember that although aluminium might be put into the pot it did not necessarily appear in the product, as it might be removed by chemical reaction during the process. The latter point was supported by Dr. E. Riley and Mr. Stead.

Mr. Galbraith's two contributions were next read and discussed, but do not call for any special mention. Finally, Mr. A. Rollet's paper was read, in which his process of obtaining purified metal for castings was described. The process was illustrated by diagrams, and may be said briefly to consist of eliminating from pig-iron, to be used for the manufacture of particular qualities of steel, sulphur, phosphorus, and silicon. The pig is placed in a special cupola, and is maintained at a very high temperature under a double action, slightly reducing and slightly oxidizing, in the presence of a slag obtained by admixtures of limestone and lime, iron ores, and fluor-spar. By the arrangement of the cupola the metal is separated from the slag as soon as they are removed from the action of the blast in tapping. In this way the phosphorus already eliminated is prevented from going back into the metal, and too great a recarburization is also avoided. The elimination of sulphur is complete up to 99 per cent. and even more; that of phosphorus amounts to 80 or 85 per cent., or even 90 per cent. and more.

A short discussion followed the reading of the paper. The only important point brought forward, however, was a statement by Mr. Hugh Bell that, at Clarence, they had been carrying on a process almost identical with that described by the author. Had he, the speaker, been aware that the plan was in use elsewhere, and had he known a paper was to be read on the subject, he would have come provided with certain figures bearing on the matter.

The meeting then broke up after the usual votes of thanks had been duly passed.

The autumn meeting of the Institute is this year to be held in America. The meeting will be held in New York, and we hear rumours of vast preparations that are being made by the hospitable metallurgists and engineers of the United States to welcome their British *confrères*. Members are left to make their own way to New York, but upon landing they become the guests of the American Institute of Mining Engineers. From an outline programme we have seen, it would appear that the only limit to the excursion will be the time at the disposal of members, which, those who know American hospitality best will agree, is sure to be exhausted long before the good-nature of their hosts.

We should have stated before that Mr. W. D. Allen, of Sheffield, this year has been awarded the Bessemer Gold Medal. Mr. Allen was associated with Sir Henry Bessemer in the manufacture of Bessemer steel from the very first. Indeed, he may be said to have been present at the birth of the invention, and was fully acquainted with the whole process before a single patent was taken out.

A MONUMENT TO A FAMOUS JAPANESE CARTOGRAPHER AND SURVEYOR.

THE *Japan Weekly Mail* contains a report of the unveiling of a monument in Tokio on December 14, 1889, to the memory of Ino Chukei, a Japanese cartographer and surveyor of the early part of the present century. The ceremony was performed by Prince Kitashirakawa, President of the Tokio Geographical Society. The name of Ino Chukei was first made familiar to the Western world by Dr. Naumann, the organizer, and for many years the head of the Geological Survey Bureau of Japan. More lately, Dr. Knott wrote two short biographies of Ino, the one published in the Transactions of the Asiatic Society of Japan (vol. xvi., 1888), and the other as an appendix to the memoir on the recent Magnetic Survey of Japan, published in the Journal of the College of Science, Imperial University (vol. xi., 1888). Ino was by profession originally a brewer, and did not begin his scientific life till he was past fifty. The story of the enthusiastic septuagenarian travelling over the length and breadth of Japan with his quadrant, his azimuth circle, his compass, and his clock is almost a romance. His latitude measurements are still of importance to the cartographer, and his map of Japan has formed the basis of every map since constructed. He finished his grand survey in 1818, after 17 years of travelling and observing. And now, nearly seventy years after his death, a lasting memorial has been raised at Shiba, in Tokio. The ceremony of unveiling the monument began at 2 p.m. on December 14, in the presence of a large company. Amongst those present were Prince Kitashirakawa, Viscount Sano, Viscount Enomoto, Admirals Akamatsu, Nakamuta, and Yanagi, Mr. Hanabusa (Councillor), Mr. Arai, Director of the Meteorological Office, Mr. Watanabe, President of the Imperial University, many of the University Professors, and others. The Chinese Representative, the German Minister, M. Dautremer, of the French Legation, and Profs. Burton, Divers, and Knott, may be named as the diplomatic and scientific representatives of foreign nations. The Naval Band was in attendance, and filled the intervals between the different parts of the celebration with selections of music. Four Shinto priests first went through a religious ceremony, which consisted chiefly of purificatory rites, and an invocation to the spirit of Ino. Mr. Watanabe then read a report, giving a history of the movement, which originated seven years ago with the members of the Tokio Geographical Society, and culminated in the ceremony of the day. The original desire had been to put up the monument on the site of the spot where Ino made the first observations in his grand survey—that is, the point through which the zero meridian was taken. This was at Shinagawa. But it had been found more convenient to raise the memorial at Shiba, within sight of this first station. The monument, designed by Prof. Tatsuna, of the Imperial University, and cast in bronze at the Kawaguchi Foundry, had cost nearly 3800 dollars. The whole of the expenses had amounted to about 4000 dollars, which had been met by voluntary subscriptions from the members of the Geographical Society and many others who desired to contribute their mite. The monument, a graceful obelisk of a dull green tint, was unveiled by Prince Kitashirakawa, a translation of whose speech runs thus:—"What an achievement in cartography was that of learned Ino Chukei! During the eras of *Kansei* and *Bunsei* (1790 to 1820), when Japan, at peace within her own borders, isolated from intercourse with the outer world, divided into a number of mutually-secluded fiefs, and, undisturbed by the cares of coast defence, was content with her own littleness, Ino, his fiftieth year already passed, commenced the study of geodesy, and, equipped with instruments of his own manufacture, devoted eighteen years of toil and suffering to the survey of the empire, bequeathing to posterity the memory of a truly great work. From the point of view of strategical advantage, from the point of view of the progress of civilization, from a domestic as well as from a foreign point of view, Ino undoubtedly was a credit to his country. His name is on the lips of the whole nation. The Emperor himself has bestowed posthumous rank on him and presents on his descendants. Japanese and foreigners have contributed to erect to his memory a monument of dimensions unparalleled in Japan. And it is a privilege conferred on me in this enlightened era that, as President of the Tokio Geographical Society, I am permitted to speak of his achievements and to unveil his monument. I rejoice greatly to take part in this imposing ceremony, and I am persuaded that the spirit of Ino in heaven will share the satisfaction which his posterity must feel on such an occasion. Reverentially, on behalf of this Society, I unveil the monument. May the fame of the illustrious dead grow with the growth of our country's civilization."

After some minutes' interval, Viscount Sano advanced to the foot of the steps that lead up to the pedestal, and introduced to the audience the great-great-grandson of Ino, who bowed and expressed the gratitude of the family for the honour done to their ancestor. Viscount Sano then gave a short biographical sketch of Ino, and an account of his great labours, for which he had earned the never-dying gratitude of his countrymen. This ended the ceremony. Later on, in the rooms of the Geographical Society, a select party assembled to inspect the rude instruments with which Ino carried out his observations. The obelisk is very graceful in form, and beautiful in its setting. As already mentioned, the colour is pleasing, and the inscription is artistic as only an ideographic inscription can be. The monument is 34 feet high, the obelisk itself being 27 feet. A flight of steps ascends to a square platform of masonry in the centre of which the pedestal rests. A railing, the bars of which are curved and puckered up so as to represent sea and clouds according to a common Japanese convention, runs round the outer edge of the platform and down the sides of the steps, allowing free ingress and egress to the pedestal and obelisk. The obelisk faces nearly south, and in its back is a door by which access can be gained to the interior. It is intended to place inside the instruments already spoken of, which were used in Ino's survey.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 1.—"The Development of the Sympathetic Nervous System in Mammals." By A. M. Paterson, M.D.

At the present time two opposite views exist among embryologists regarding the development of the sympathetic system. In both, the segmental formation of the sympathetic cord is upheld. According to the view of Remak and others, it is mesodermal, and formed *in situ*. According to the other view, it is ectodermal. Balfour and Onodi, who have maintained the latter view, differ, however, as to the fundamental origin of the sympathetic system—Balfour regarding each sympathetic ganglion as an offshoot from the spinal nerve, while Onodi considers it as a direct proliferation from the spinal ganglion.

For the present research, mammalian embryos were exclusively employed. The stage in development was first considered in

which the sympathetic system was plainly visible; and from this point the earlier and later steps in the process were traced.

The first event to occur is the formation of the main sympathetic cord, which arises in the mesoblast on either side of the aorta, as a solid, unsegmented rod of fusiform cells produced by the differentiation of cells *in situ*, and not at first connected with the spinal nerves. In front, it ends abruptly at the level of the first vertebral segment; behind the suprarenal body (to which it sends a considerable cellular bundle) it becomes indistinct, terminating at the level of the hind limbs.

This cellular column is, secondly, connected to the spinal nerves by the formation of the white *rami communicantes*. This is effected by the gradual growth of the inferior primary divisions of the nerves, and their final division into *somatic* and *splanchnic* branches. The splanchnic branch extends into the splanchnic area, where it meets and joins the cellular sympathetic cord. In the anterior part of the thorax it appears to end wholly in the cord; in the posterior thoracic and lumbar regions it divides into two parts, of which one joins the cord, the other passes beyond it. In both cases the fibres joining the cord are directly connected with the component cells. Behind the loins the splanchnic branches cease, and in the neck they do not join the sympathetic cord.

The formation of ganglia in the main sympathetic cord occurs subsequently, and is due to (1) the function of the splanchnic branches, the accession of a large number of nerve-fibres at the point of entrance, and the consequent persistence of the component cells (which are joined by these nerves) as ganglion cells; and (2) the anatomical relations of the cord to the bony segments, vessels, &c., over which it passes, and which indent it at certain points. This view is supported by the evidence obtained from dissections of human embryos in the 3rd, 4th, 5th, and 6th months, where the cord forms a band, constricted irregularly at considerable intervals, and from the adult structure, where the "segmentation" of the sympathetic cord is apparent rather than real.

The cervical portion of the embryonic sympathetic cord separates at the origin of the vertebral artery into two unequal parts. The smaller forms a fibro-cellular cord, and accompanies that artery as the vertebral plexus; the larger portion becomes constricted off from the main sympathetic cord by the formation of a fibro-cellular commissure, and forms the "superior cervical ganglion." When the middle cervical ganglion is present, it may be looked upon as a mass of the original cells of the sympathetic cord which have been included in the growth of the commissure.

Posteriorly the sympathetic cord gradually extends from the level of the hind limbs, until in older embryos it can be traced for a considerable distance along the middle sacral artery. It is not joined by splanchnic branches behind the loins.

The peripheral branches from the sympathetic cord arise as cellular outgrowths which accompany the parts of the splanchnic branches which do not join the sympathetic cord into the splanchnic area. They form considerable nerves, which follow the main vessels, and produce parts of the splanchnic nerves, the solar plexuses, &c., as well as the medullary portion of the suprarenal body. The gray *rami communicantes* appear to arise in the same way, and to belong to the same category.

The main conclusions derived from the above investigations are that in its development the sympathetic cord in mammals is mesoblastic, formed *in situ*, and primarily unsegmented, and unconnected with the spinal nervous system.

Linnean Society, May 1.—Mr. J. G. Baker, F.R.S., Vice-President, in the chair.—Mr. Miller Christy exhibited and made remarks on specimens of the so-called Bardfield oxlip, which he had found growing abundantly not only in the neighbourhood of Bardfield, Essex, but over a considerable area to the north and west of it.—Mr. Buffham exhibited under the microscope specimens of *Myristrichia claviformis* with plurolocular sporangia, and conjugation of *Rhabdomena arctuatum*, found upon *Zostera marina*.—The Rev. Prof. Henslow exhibited a collection of edible Mollusca which he had recently brought from Malta, and described the native methods of collecting and cooking them.—Prof. Stewart exhibited some spirit specimens of a lizard, in which the pineal eye was clearly apparent.—Mr. Sherring exhibited a series of excellent photographs which he had taken near Falmouth, and which showed the effects of climatic influence on the growth of several subtropical and rare plants cultivated in the open air.—A paper was then read by Prof. W. Fream, on a quantitative examination of water-meadow herbage.—This was followed by a paper from Mr. R. I. Pocock, on some Old World species of scorpions.

Zoological Society, May 6.—Prof. W. H. Flower, F.R.S., President, in the chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the month of April 1890; and called special attention to two examples of Simony's Lizard (*Lacerta simonyi*) from the rock of Zalmo, Canaries, obtained by Canon Tristram, F.R.S., and presented to the Society by Lord Lilford.—Mr. Sclater exhibited and made remarks upon the stuffed head of an Antelope, shot by Commander R. A. J. Montgomerie, R.N., of H.M.S. *Boadicea*, in June 1890, near Malimdi, on the East African coast, north of Zanzibar. Mr. Sclater referred this head to what is commonly called the Korrigum Antelope (*Damalis senegalensis*).—Prof. Howes made remarks on a dissection of the cephalic skeleton of *Hatteria*, and pointed out some features of special interest exhibited by this specimen. These were the presence of a pro-atlas and the existence of vomerine teeth, as in *Palæohatteria*.—Two letters were read from Dr. Emin Pasha, dated Bagamoyo, March 1890, and announced that he had forwarded certain zoological specimens for the Society's acceptance.—Mr. H. Seebohm exhibited and made remarks on a specimen of the Eastern Turtle (*Turtur orientalis*), killed near Scarborough, in Yorkshire.—Prof. F. Jeffrey Bell read the first of a series of contributions to our knowledge of the Antipatharian Corals. The present communication contained the description of a particularly fine example of the Black Coral of the Mediterranean, and an account of a very remarkable Antipathid from the neighbourhood of the island of Mauritius.—A communication was read from Mr. E. N. Buxton, containing notes on the Wild Sheep and Mountain Antelope of the Algerian Atlas, taken during a recent excursion into that country. These notes were illustrated by the exhibition of fine mounted specimens of the heads of these animals.—Mr. R. Lydekker read a note on a remarkable specimen of an antler of a large Deer from Asia Minor, which he was inclined to refer to an abnormal form of the Red Deer (*Cervus elaphus*).—Mr. F. E. Beddard read a paper on the minute structure of the eye in some shallow-water and deep-sea species of the Isopod genus *Arcturus*. He pointed out that in all the deep-sea forms there was some change in the visual elements which indicated degeneration.—Mr. E. T. Newton gave an account of the bones of some small birds obtained by Prof. Nation from beneath the nitrate beds of Peru. These bones seemed to occur in considerable abundance, and nearly all appeared to belong to one small species of Petrel, which it was thought most nearly resembled *Cymochorea leucorrhoa* or *C. markhami*, the latter of these being now found living on the coast of Chili.—A communication was read from Dr. Mivart, F.R.S., containing notes on some singular Canine dental abnormalities.—Mr. H. Elwes read descriptions of some new Indian Moths.

Chemical Society, May 1.—Dr. W. J. Russell, F.R.S., President, in the chair.—The following papers were read:—An investigation of the conditions under which hydrogen peroxide is formed from ether, by Prof. W. R. Dunstan and Mr. T. S. Dymond. The authors have investigated the conditions under which hydrogen peroxide is formed from ether (compare Richardson, Chem. Soc. Proc., 1889, 134), and found that ordinary ether, prepared from methylated spirit, yields hydrogen peroxide when exposed for several months to sunlight or the electric light. Contrary, however, to the usual statements, pure ether (either wet or dry) and ordinary ether which has been purified by treatment with dilute chromic acid do not give a trace of hydrogen peroxide when exposed to light under similar conditions. An experiment shows that neither water nor dilute sulphuric acid form hydrogen peroxide when exposed to light in contact with air; the authors refer the production of the peroxide from ether to the presence of a minute quantity of some impurity in the ether employed. Hydrogen peroxide is formed when ozone acts on ether in the presence of water, and is also produced under certain conditions during the slow combustion of ether in contact with water.—Paradesylphenol, by Dr. F. R. Japp, F.R.S., and Mr. G. H. Wadsworth.—Note on Benedikt's acetyl values, by Dr. J. Lewkowitsch.

Mathematical Society, May 8.—J. J. Walker, F.R.S., President, in the chair.—The President announced that a member of the Society, Lieut.-Colonel J. R. Campbell, had asked to be allowed to give a donation of £500 to the Society, the sum to be invested, or otherwise made use of, for the good of the Society, in any way the Council should judge best. On the

motion of the Treasurer, (A. B. Kempe, F.R.S.), seconded by S. Roberts, F.R.S., the following resolution was carried unanimously: That the cordial thanks of the London Mathematical Society be given to Lieut.-Colonel Campbell for his generous gift of £500 to the general fund of the Society.—The following communications were made:—On the function which denotes the excess of the divisors of a number which $\equiv 1$, mod. 3, over those of a number which $\equiv 2$, mod. 3, by Dr. Glaisher, F.R.S.—A table of complex multiplication moduli, by Prof. Greenhill, F.R.S..—On bicircular quartics, by R. Lachlan.—On the genesis of binodal quartic curves from conics, by H. M. Jeffery, F.R.S.—On the arithmetical theory of the form $x^3 + ny^3 + n^2z^3 - 3nxyz$, by Prof. G. B. Mathews.

PARIS.

Academy of Sciences, May 6.—M. Hermite, President, in the chair.—Heats of combustion of the principal nitrogen compounds contained in living bodies, and their *rôle* in the production of animal heat, by MM. Berthelot and André. The data and results are given for sixteen nitrogenous bodies. The average heat of combustion is 9400 cal. for fatty bodies, 5700 cal. for albumenoids, and 4200 cal. for carbohydrates, taking 1 gram of each substance. The conclusion is drawn that a weakening of the organism with diminution of power of consumption of the food digested shows itself first by general deposition of the most difficultly eliminated substances, fatty matters, then by failure to get rid of nitrogenous bodies, and finally by incapacity to consume the carbohydrates.—Some remarks on the subject of spherical functions, by M. E. Beltrami.—Remarks on the loss of virulence in cultures of *Bacillus anthracis*, and on the insufficiency of inoculation as a means of estimating it, by M. S. Arloing. It is known that in a culture of the *Bacillus anthracis* left to itself the virulence after a time disappears. The author gives details of the phenomenon and some results of an examination of various cultures.—MM. Bertrand, Tisserand, and Poincaré reported on a memoir by M. Cellérier entitled "On Variations of Eccentricities and Inclinations." The memoir deals with equations of movement, planetary perturbations, the development of the perturbing function, the study of secular variations, and the differential equations which define them.—On fields of magnetic rotation, by M. W. de Fonvielle.—On algebraical integrals of differential equations of the first order, by M. Painlevé.—Solar phenomena observed during 1889, by M. Tacchini. The distribution in latitude of protuberances, faculæ, spots, and eruptions is given.—On the polarization of electrodes, by M. Lucien Poincaré. The author shows that in the case of melted salts the maximum polarization decreases with the temperature, and becomes *nil* at the temperature of decomposition of the salt, the change is gradual with silver poles, but with gold electrodes there is a sudden fall at the point of decomposition of the electrolyte. Admitting that the maximum of polarization is equal or superior to the equivalent of the energy expended in the electrolytic action, the results point to the theory that an elevation of temperature tends to dissociate a salt by the separation of the two ions of which it is composed, just as occurs, according to M. Arrhenius, in a weak solution.—On the preparation and properties of tetrafluoride of carbon, by M. H. Moissan.—On the reduction of nitric acid to ammonia and a method of estimation of this acid, by M. E. Boyer. The author indicates the exact conditions under which nitric acid may be entirely reduced to ammonia when acted upon by hydrogen liberated in the solution by the action of Zn upon hydrochloric acid, and gives analyses which show that his method yields trustworthy quantitative results.—On the molecular refracting power of salts in solution, by M. E. Doumer. It is shown that the law of molecular refraction is best exemplified when one considers the solutions in a state of dilution such that the density of the salt in the solution, taken in relation to the density of hydrogen, may be equal to the molecular weight of the salt.—The action of oxygenated water upon the oxygen compounds of manganese; Part 2, action upon permanganic acid and the permanganates, by M. A. Gorgeu.—On the amethylcamphophenolsulphonate and a derived tetranitrated yellow colouring-matter, by M. P. Cazeneuve.—Note on tridymite and christobalite, by M. Er. Mallard.—On the zeolites of gneiss from Cambo (Basses Pyrénées), by M. A. Lacroix. It is noted that the zeolites are remarkable for their abundance and the beauty of their crystals. They occur in two distinct beds: (1) in acid gneisses, (2) in basic gneisses. Descriptions of the crystals are given.—On a new method for the analysis of straw, by M. Alexandre Hébert.—On the *rôle* of green manures as nitrogenous dressing, by M. A. Muntz. The author concludes from the results of some experiments that the efficacy of green manures as nitrogenous dressing depends especially on the facility with which the fresh vegetable matters allow the nitrification of the proteids and on the favourable influence which they exercise on the physical properties of soils.—Experiments relative to the transmissibility of hæmoglobinuria to animals, by M. V. Babes.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

A Class-Book of Geography: W. B. Irvine (Relfe).—A Hand-book of European Birds: J. Backhouse (Gurney and Jackson).—Larva Collecting and Breeding: Rev. J. S. St. John (Wesley).—A Course of Lectures on the Growth and Means of Training the Mental Faculty: Dr. F. Warner (Camb. University Press).—Pure Logic, and other Minor Works: W. S. Jevons (Macmillan).—Terminologia Medica Polyglotta: T. Maxwell (Churchill).—A Guide to the Exhibition Galleries of the Department of Geology and Palæontology in the British Museum (Natural History), Parts 1 and 2 (London).—Geologisk kart over de Skandinaviske Lande og Finland: H. Reusch (Kristiania).—The Elements of Machine Design; Part 1, new edition: W. C. Unwin (Longmans).—Annual Report of the Department of Mines, N.S.W., for the year 1888 (Sydney, Potter).—Seventh Annual Report of the U.S. Geological Survey 1885-86: J. W. Reusch (Kristiania).—Report of Mr. Tebbutt's Observatory, 1889: J. Tebbutt (Sydney).—Notes on Electric Lighting: Rev. G. Molloy (Dublin, Gill).—Imperial College of Agriculture and Dendrology, Tokyo, Japan, Bulletin No. 7: Y. Kozai (Tokyo).

CONTENTS.

THURSDAY, MAY 22, 1890.

THE FUTURE UNIVERSITY FOR LONDON.

THE latest news of the negotiations between the various institutions whose co-operation is necessary for the establishment of a satisfactory system of graduation for London University students is decidedly good. Lord Cranbrook, as the Minister in charge of educational legislation, has intimated to the University that he is prepared to take up the question, and is in expectation of receiving an application for a new charter for the purpose of instituting such a system. The scheme which was drafted by a Committee of the Senate, which was communicated to the University Colleges and to the Royal Colleges of Physicians and Surgeons, and was under discussion at the meeting of the Convocation on the 14th inst., contains some novel features, which show that the University is prepared to move forward, in order to meet the immediate necessities of the situation, beyond the recommendations of the abortive Royal Commission of 1888, and far beyond the *non possumus* of the University witnesses before that Commission. It practically embodies the concession of a separate system of graduation, to be conducted by an administrative Committee of the Senate, upon which the teaching institutions shall be adequately represented, independently of the present system of graduation by open examinations. It contains a further excellent suggestion, that this present system shall also be conducted by a Committee of the Senate, the Senate itself remaining the ultimate authority for both systems, but leaving the details of administration to the two Committees. This plan, which is due to the initiative of the Senate Committee, appears likely to meet objections of Convocation and of the country University Colleges, and must render it easier for the London institutions to accept the Senate as the ultimate authority on the teaching side.

Accordingly we are not surprised to hear that the University Colleges have expressed themselves ready to accept the proposal, and to abandon, subject to a satisfactory settlement of details, their petition for a separate University. We trust that a spirit of mutual concession will continue to sway the counsels of the contending parties, and that we may be able to hail the establishment of the teaching side of the University of London, which will be the real University for London, during the present year. The new system of graduation will follow the teaching in the London colleges and schools, which will be organized for the purpose by the London Committee of the Senate. We trust that it will be complete in itself, and that its administrators will receive powers to develop it without unnecessary restrictions. The development, in particular, by means of what is known as University Extension lectures has been recognized by the Senate Committee as work which properly belongs to the teaching side for London, and should be placed under the London Committee. This removes a difficulty, which might have been serious, in the way of agreement with the University Colleges. Another, which arose from the embodiment by the Senate Committee in their scheme of the Scottish system of examinations—a system considered in England to leave too much to the discretion of the individual professor, and unsuited to the circumstances of London, where there will be, in most subjects, at least two professors—has also, as we are informed, been removed by concessions from the Senate Committee.

Of the points which remain for settlement the most important are the composition of the Committee for London, and the place in the University of the London Medical Faculty. The first is matter for mutual discussion and arrangement between the various institutions and interests concerned. The University Colleges claim that, besides the "Faculty" representatives, or professors, there shall be three representatives upon the Committee of the Council of each of the Colleges. Since the University is not willing that there should be any members on the Committee who are not also members of the Senate, this involves the further point that the six Council members shall be admitted to the Senate. By our latest advices the Senate Committee appear not unwilling to make this further concession, which is deemed indispensable by the Colleges. It can hardly be said to be an extravagant demand, if the importance of the two great Colleges in the teaching system is considered.

With regard to the Medical Faculty, the representatives of the Royal Colleges of Physicians and Surgeons, and those of the hospital schools unconnected with a University College, besides the two University Colleges, will be consulted. The plan recently put forward by a Committee of the Royal Colleges, which had not been in communication with the University Colleges, involved the constitution of a Joint Committee of the University and the Royal Colleges only, for the purpose of administering a system of "pass" degrees in medicine, in which the examinations of the Conjoint Board of the Royal Colleges should be recognized as an equivalent for the present intermediate examinations and B.M. examinations of the University, and a new M.D. degree should afterwards be given, upon a University examination. We are glad to find that the proposal of the Royal Commissioners to hand over the preliminary scientific examination to the Royal Colleges, which has been condemned in these columns, is entirely disapproved by the Royal Colleges themselves. The severance of the scientific education of medical students from that of scientific students generally is to be deprecated in the interests of scientific study. The same argument seems to us to make for the inclusion of the system of medical graduation for London students in the work of the general London Committee; and we should by no means view with favour the proposal for assigning it to a separate Committee, whether constituted jointly by the University and the Royal Colleges, or as a third Committee of the Senate. In either case representatives of the Royal Colleges and of the medical schools may properly find places on the Senate. Why should they not also form part of the General Committee for London, which would thus become the single administering body for all the Faculties, so far as the teaching side was concerned? The proposal of the Royal Colleges to limit the medical degrees, upon the teaching side, to "pass" degrees, and to bar the University in this respect from conferring honours, appears inadmissible. It probably would not have been made by the Royal Colleges had they been aware of the willingness of the Senate Committee to concede the

point to the University Colleges, so far, at all events, as regards honours in arts and science.

We are informed by a legal correspondent that a strong Committee has been formed at Lincoln's Inn to promote reforms in legal education. We trust this may prove the first step to the constitution, on the teaching side of the University, with the co-operation of the Inns of Court, of a real Legal Faculty, on a basis similar to that above recommended for medicine. To separate the professional Faculties from the academical, in a University of the nineteenth century, savours of anachronism.

RECENT ORNITHOLOGICAL WORKS.

Classification of Birds; an Attempt to diagnose the Subclasses, Orders, Sub-orders, and some of the Families of Existing Birds. By Henry Seebohm. Pp. i–xi., 1–53. (London: R. H. Porter, 1890.)

A Hand-book of European Birds, for the use of Field Naturalists and Collectors. By James Backhouse, Junr. Pp. i–viii., 1–334. (London: Gurney and Jackson, 1890.)

THE most important ornithological work which has recently appeared is undoubtedly Mr. Henry Seebohm's "Classification of Birds." Any attempt to arrange the class "Aves" is always warmly welcomed by ornithologists; and whether they agree or not with all Mr. Seebohm's conclusions, they have every reason to be grateful to him for an honest effort to diagnose the existing orders of birds. It has been known to most of us that Mr. Seebohm has been engaged, with his usual energy, in a close study of avian osteology for the last two years, and the present "Classification" is the result of his original studies, combined with a careful digest of the work of his predecessors in the same field—Parker, Fürbringer, Garrod, Forbes, and others.

The author starts with a high purpose, and with a resolve that diagnoses shall be found which shall hold good for each group of birds, and that the combination of characters set forth shall be diagnostic of that group, and of that group alone. No one, therefore, can grumble at the arrangement, because the order can be altered at will, each order and sub-order possessing their absolutely special characters. Two schemes for the higher classification of birds are proposed. In the first one the author recognizes six sub-classes, as follows:—I. Passeriformes; II. Falconiformes; III. Coraciiformes; IV. Anseriformes; V. Galliformes; and VI. Struthioniformes.

In his "Alternative Scheme" he reduces the number of sub-classes into *five*, by merging the Falconiformes, the Anseriformes, and the Galliformes into the sub-classes Ciconiiformes and Galliformes, the latter taking in the Lamellirostres of the first classification, and sending in return the Tubinares and Impennes back to the Ciconiiformes.

The condition of the young at birth forms the groundwork of this second method of classification, which the author approves, but the subject is treated in a method different from that of Sundevall, who also thought highly of the condition of the nestling bird as an element of primary classification, but, according to Mr. Seebohm, he attached an exaggerated importance to some of the facts. That the character of the nestling is bound to play a significant part in the classification of birds we can well understand, but at present the various developments of the downy young are, we believe, but imperfectly understood. Thus we may remark that in the Passeriformes we know at least two exceptions to their diagnosis as given by Mr. Seebohm, viz. in the Shore Lark (*Otocorys alpestris*), and in a curious bird from Ecuador, *Ptilochloris buckleyi*, belonging to the family *Pipridæ*. Other examples will doubtless be found, and yet closer examination will probably demonstrate that the downy stage through which these Passerine birds pass will be of a different fundamental character from the downy stages of other birds.

There can be but little doubt that of the two schemes provided by Mr. Seebohm the second one is the best, but a stumbling-block at first sight appears to be the position of the *Columbæ* in the Passeriformes, and that of the *Cathartes* (*lege* Cathartides) in the Coraciiformes with the Kingfishers and Hornbills. It is perhaps the novelty of these allocations that causes our hesitation in accepting them, for after all a Turkey Vulture and a Ground Hornbill (*Bucorax*) have considerable resemblance. In any case Mr. Seebohm gives characters for the diagnosis of all his Orders and Sub-orders, and their linear arrangement can be shifted at will. Each order and sub-order is not only defined, but a table accompanies every one of them, showing the whole of the thirty-six minor divisions, exhibiting by an asterisk the want of any specified character, and so narrowing the issue of definition in each instance. The author is greatly to be congratulated on the result of his two years' labour, which will doubtless be the stepping-stone to further treatises on the classification of birds.

We cannot congratulate Mr. James Backhouse on his "Hand-book of European Birds." The author's intention doubtless is good, but though "many of the finest bird collections in the Kingdom have been carefully examined, and the best modern authorities have been consulted," the result of all this compilation is not satisfactory, and a want of practical acquaintance with the manner in which a "Hand-book" should be written is apparent at every step. We fear that the outline figure of a bird, drawn by Mr. R. E. Holding, in order to show the nomenclature of the different parts of a bird, will not commend itself to any experienced field naturalist or collector, who will probably know more of his subject than did the artist who perpetrated this figure. We will do no more than point out that the "cervix" is called the "hind neck" by most ornithological writers, that the "malar region" is generally spoken of as "the cheeks," that the positions of the "breast," "abdomen," and "anal region" are all placed wrongly in the figure, and that the "crissum" is not the same as the "lower tail-coverts." The divisions of the back are also wrongly defined. Luckily, the author himself does not recognize the terminology of his own "bird-map," or the confusion of parts would have been disastrous.

We had fondly hoped that, having started the "Birds of Europe" in 1871 (since completed by Mr. Dresser), with the idea that a work of that character should include all the species of the Western Palæarctic region, which is at least a natural division of the globe, it would not

occur to future authors to return to the old idea of treating the avifauna of Europe on political ideas, and fencing in the ranges of the birds with political boundaries. Yet it is on these old lines that Mr. Backhouse has written his "Hand-book," and he must be held responsible for a very retrograde step. From his preface, with the short definition of the six zoogeographical divisions of the earth, one would expect to find that he recognized the value of writing on the birds of a well-defined zoological area, but a glance at the countries which he assigns to the Ethiopian and African regions shows that he does not really understand the subject of geographical regions, for, after stating that the Western Palæarctic sub-region includes the countries *west* of the Jordan, he apparently wishes us to believe that Palestine *east* of the Jordan belongs to the Eastern Palæarctic sub-region, while Asia Minor is to remain in the western part. We should like to know where the regional differences between Asia Minor and Persia, and, for that matter, Palestine and Syria, begin and end. Arabia seems to be left out in the cold, finding a place neither in the Palæarctic nor in the Ethiopian regions, while the Indian region includes Asia south of the Himalayas with the Indo-Malayan Islands and Formosa, as well as *Madagascar!* With such crude notions as to the limits of the regions which adjoin the Palæarctic, it is not to be wondered at that Mr. Backhouse's ideas of the natural limits of the latter are also ill defined. The mischievous results of these notions of the limits of "Europe" are seen in the appendices of North American birds which are "*stated*" to have occurred in Europe. Many of the birds mentioned in his list have undoubtedly occurred more than once, and the incompleteness of the plan of the work is shown by their omission from the body of it, because these species may occur again at any time to the "field naturalist" or "collector," for whom the author specially caters, and these will look in vain for them in this "Hand-book." The same with the list of Asiatic and African species which are *stated* to have occurred in Europe. Many of them *have* occurred in Europe, beyond the shadow of a doubt, and *Certhilauda duponti* (of *C. lusitanica* the author apparently knows nothing), *Sturnus purpurascens*, and *Falco minor*, have as much right to be considered European birds (even in Mr. Backhouse's acceptation of the term), as *Picus lilfordi* or *Cypselus pallidus* (whose range is *not* "probably similar to that of *C. apus*," or anything like it).

The main idea running through Mr. Backhouse's "Hand-book" seems to be the same as was exemplified in Colonel Irby's "Key List to British Birds," but we greatly prefer the plan of the latter pamphlet for its method of execution to the more ambitious work of Mr. Backhouse, wherein most of the mistakes of Dresser's "Birds of Europe" are reproduced, even to the omission of the Astrachan Horned Lark (*Otocorys brandti*)! Besides the faults we have noted, all of which are easily capable of rectification in a future edition, there is one cardinal defect in this "Hand-book," and that is in the assumption that the "field-naturalist" and "collector," for whom the author writes, is minutely acquainted with Palæarctic *genera*, and will know instinctively whether he has a *Hypolais*, an *Acrocephalus*, or a *Lus-ciniola* in his hands.

R. BOWDLER SHARPE.

CRIMINAL ANTHROPOLOGY.

The Criminal. By Havelock Ellis. Illustrated. (London: W. Scott, 1890.)

CRIMINAL anthropology has of late years attracted much attention abroad, where its problems have been largely and often very loosely discussed. Mr. Havelock Ellis performs the useful task of making English readers acquainted with the results. It cannot be said that much progress has been made on the psychological side of the subject since the publication of Despine's "Psychologie" in 1868, but the main conclusions of that author have been abundantly confirmed. On the physical side, numerous dissections and measurements seem to have led to no well established and important fact; they have, however, narrowed the limits within which speculation may legitimately ramble. It is well ascertained that many persons are born with such natures that they are almost certain to become criminals. The instincts of most children are those of primæval man; in many respects thoroughly savage, and such as would deliver an adult very quickly into the hands of the law. The natural criminal retains those same characteristics in his adult life. The author has a very true but not complimentary passage upon the ways of children. He says that the child lives in the present, the desire of the moment blotting out everything else from his mind. That he has no foresight to restrain him from acting according to impulse. That he is a thorough egoist, and will commit any enormity to obtain what he wants. That he is cruel and enjoys the manifestations of pain. That he is a thief for the gratification of his appetites, chiefly of gluttony; and that he is an unscrupulous and often cunning liar, not hesitating to put the blame on innocent persons when his own misdeeds are discovered. In the large majority of our countrymen the savagedom of childhood becomes gradually in part repressed, in part outgrown, and in part transformed. Discipline is one agent, another is the larger growth of sympathetic feelings, and another is the education of a habit of forethought, which prompts selfishness to be wise, and induces many persons to assume throughout life the appearance of virtues for which they have no care, solely through the fear of social or legal punishment. We may freely allow that everybody is liable under some circumstances to fall into crime, for, in the words of the liturgy, "we are set in the midst of so many and great dangers that by reason of the frailty of our nature we cannot always stand upright," but the difference between ordinary persons and natural criminals is that the latter are unable to stand upright even under favourable conditions. There are numerous human beings who have an instinctive aptitude to various forms of ill-doing, no sense of remorse for the sufferings they may have caused, and who possess too little forethought and self-restraint for the fear of retribution to become effective. Abundant evidence of all this is to be found in Mr. Ellis's book, and there seems to be a consensus among experts as to its trustworthiness.

It is easy to understand that ordinary men who are thrown among criminal associates will soon acquire their furtive expression and other peculiarities of demeanour; but after making all allowance for these acquired characteristics there remain certain natural ones that

predominate among all large groups of criminals. These are well set forth by Mr. Ellis, chiefly under the titles of cranial characteristics, physical insensibility, moral insensibility, and emotional instability. A fresh indication of frequent misshape in their heads may be derived from the three composite portraits of criminals (who were by no means of a bad order) that are given in this volume. Here the outlines of the heads of the composites are very hazy, testifying to large and *various* differences in the component portraits. These composites show no prevalence of any *special* deformity in head or features.

The hope of the criminal anthropologist is to increase the power of discriminating between the natural and accidental criminal. He aims at being able to say with well-founded confidence of certain men that it is impossible to make them safe members of a free society by any reasonable amount of discipline, instruction, and watchfulness, and that they must be locked up wholly out of the way. Also, to say of some others that it would be both cruel and unwise to treat them as ordinary criminals, because they have been victims of exceptional circumstances: they are not naturally unfit, and therefore still admit of being turned into useful members of society. Extracts are given in this book from the official reports of the prison at Elmira in the United States, where experiments are made in educating prisoners of the latter class. They describe a system of massages and Turkish baths three times a week, courses of literature, æsthetics, and ethics, including a study of Jowett's translation of the "Republic" of Plato, and of the works of Herbert Spencer, together with a gymnasium and a drum corps, suggesting to the unprepared reader a chapter in Gulliver's account of the institutions of Laputa.

FRANCIS GALTON.

ELEMENTARY PHYSIOGRAPHIC ASTRONOMY.

Lessons on Elementary Physiographic Astronomy. By John Mills. (London: Chapman and Hall, 1889.)

THE expressions of approval of the physiography syllabus of the Science and Art Department by the British Association Committee on science teaching lend an additional interest to new text-books of this subject. The book before us covers the portion of the syllabus dealing with the movements of the earth. We believe Mr. Mills has occasionally been employed as an Assistant Demonstrator at the Normal School of Science, and on the strength of this he claims to have had four years' experience as a teacher of the subject in that institution. It is rather late for Mr. Mills to state that, "in the hope of encouraging teachers and students to make the subject a more practical one, instructions have been given for making some inexpensive apparatus," considering that all the practical work given is taken from the book of instructions supplied to students at the Normal School, and which was distributed by the authorities of the Science and Art Department to teachers throughout the country some months ago, with the sole object of encouraging practical demonstrations in classes. Anyone can now obtain the same for twopence. There are many indications that the author is only acquainted with a limited part of the subject. The article on the use of the micrometer, for example (p. 25), is sure to impart the idea that a definite fraction of an inch represents a definite amount of arc, irrespective of the telescope employed; and that, in consequence, the distance between two stars or the apparent diameter of a planet can be stated in inches; further, the zero for position angles is given as "the normally horizontal wire," which is obviously an inconstant, and therefore useless one. Wrong impressions are also given as to the functions of the "Nautical Almanac," for p. 81 distinctly implies that it is a record of actual observations, whereas it is published three or four years in advance. Again, on p. 20, it is stated that the transit circle is made to read 90° when the telescope is pointing to the Pole, and therefore that "when the telescope is directed to any star crossing the meridian we obtain the north polar distance of the star, and this being known, we can easily determine its declination," which is neither clear nor correct.

After deducting the practical instructions, the most casual comparison with Prof. Norman Lockyer's "Movements of the Earth," will show the source of inspiration of the remainder, although there is not a word of acknowledgment. The head-lines, diagrams, and occasionally the language, remind one of that book. The order of things has certainly been slightly changed, but the only result is to introduce disconnections and anticipations. The micrometer, for example, is described before the chapter on angular measurements, and the chronograph precedes that on the measurement of time. The terms "right ascension" and "declination" are frequently used, although the explanation of them is reserved for the very last page. Further instances might be multiplied almost without limit.

The whole book is of a very sketchy character, and the only redeeming feature is the excellent series of diagrams.

A. F.

OUR BOOK SHELF.

Theoretical and Practical Treatise on the Strength of Beams and Columns. By Robert H. Cousins, Civil Engineer, formerly Assistant Professor of Mathematics at the Virginia Military Institute, Lexington, Va. (London and New York: E. and F. N. Spon, 1889.)

THE author of this treatise comes forward with an attempt at an explanation of the *paradox of the beam*, which is that a beam is about double as strong as theory makes out it should be, when the resistance of the beam to bending is calculated from the tension and pressure of the fibres, considered as acting independently and without lateral support.

To account for this discrepancy, which is well known to practical men, a paper by W. H. Barlow, in the Phil. Trans., 1855, proposed a theory of lateral support of the fibres to account for the extra strength, while his careful experiments showed that the neutral plane was certainly very close to the position which theory assigned to it. Previously it had been usual for practical men to place the neutral plane at the top or bottom of the beam, and thence to calculate the strength; a better agreement with theory being thus obtained.

The author of the present treatise adopts the more modern method of taking a different tenacity and modulus of elasticity of the material for extension and for compression; his calculations are principally directed to finding the breaking load of the beam; but as all the

laws of elasticity break down long before breaking takes place, it is not surprising that he should find himself in disagreement with the results of theoretical elasticity.

A summary of the author's theory is given on p. 31, in the shape of ten hypotheses, most of which are of general acceptation, except perhaps number 8, which asserts that "The algebraic sum of the direct forces of compression and extension can never become zero;" while number 4 is redundant, and opposed to the principles of elementary statics.

After the length of time the theory of the beam has been worked at, it is natural to expect the treatment to have fallen into a conventional groove; but there is an unfamiliar appearance about the present pages, which makes it difficult to find out where the originality claimed by the author for his theory comes in; while many of his statements about the position of the neutral line (p. 27) "at the inception of the loading being at the bottom or extended side of the beam, and moved upwards by reason of the deflection and equally with it," are in direct opposition to the careful observations of Mr. W. H. Barlow.

A great many additional pages, reaching to number 166, are devoted to applications to beams of different materials, cast-iron, wrought-iron and steel, and timber; but the method is the same throughout, so that the essence of the book would go into very few pages. The treatise is a great contrast in this respect to most recent American publications on practical subjects.

A. G. G.

Chambers's Encyclopædia. New Edition. Vol. V. (London and Edinburgh: W. and R. Chambers, 1890.)

THE new volume of the present edition of "Chambers's Encyclopædia" deserves in all respects as cordial a reception as that which has been given to the preceding volumes. The editor has done his work with admirable care, selecting for the various subjects writers competent to deal with them, and setting apart for each subject, as nearly as possible, the space that properly belongs to it in accordance with the scheme of the work as a whole. Of the strictly scientific contributions, we need only say that those of them we have been able to examine are sound and concise. With regard to the articles on geology and heat, it may be enough to mention that the latter is by Prof. Tait, the former by Prof. James Geikie, to whom also have been intrusted the articles on the Glacial period and the geology of Great Britain. The climate of Great Britain is the subject of a short but luminous paper by Dr. Buchan. An excellent account of gas and gas-lighting is given by Dr. Alfred Daniell, and Prof. Ewing describes the gas-engine. Mr. Keltie contributes an interesting paper on geography, and Dr. J. S. Mackay writes with his usual clearness on geometry. Mr. F. Hindes Groome's article on the gypsies may be noted as a capital summary of many curious facts and theories. Mr. J. Arthur Thomson, in his article on heredity, displays wide reading and an impartial judgment; and Dr. J. Anderson's article on hill-forts shows how much solid information may be packed into a small space by a writer who knows his subject thoroughly.

Essays of an Americanist. By Daniel G. Brinton, M.D. (Philadelphia: Porter and Coates, 1890.)

MOST of the papers in this volume have already been printed, but some have been substantially re-written, and each of them derives an added value from the fact that it appears in association with other essays on kindred subjects. Dr. Brinton classifies the various papers under the four headings, "ethnologic and archæologic," "mythology and folk-lore," "graphic systems and literature," and "linguistic." To those who are familiar with his contributions to ethnology and anthropology we need scarcely say that the volume sets forth the results of much fresh thought and solid work. In some respects the conclusions at which Dr. Brinton has arrived differ widely from those of most other anthropologists. He holds, for example, what he calls "the specific distinction of an American race," and "the generic similarity of its languages." He is also persuaded that the tribes of this race "possessed considerable poetic feeling," and maintains "the absolute autochthony of their culture." These and other positions he defends with much ingenuity, and even those readers whom he may fail to convince will find that it is worth while to master his arguments. As an example of the thorough way in which he works at his subject, we may note his chapter on the Toltecs, whose far-famed empire he describes as "a baseless fable."

Esquisse Historique sur la Marche du Développement de la Géométrie du Triangle. By E. Vigarié. (Association Française pour l'Avancement des Sciences—Congrès de Paris, 1889.)

THIS is a full and carefully drawn-up sketch of what is sometimes called the modern geometry of the triangle. It carries on the bibliographical notice contributed by M. E. Lemoine to the same Association (1885) up to the present time, and supplies some of the lacunæ in that notice. The author appears to be very fair towards foreign mathematicians, and any deficiencies in noticing English contributions are due to there being at present no account of results which may be buried in such journals as the *Mathematician*, the *Lady's and Gentleman's Diary*, and similar works. We have little doubt that an examination of these would lead to the unearthing of many anticipations of recently obtained results.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

A Uniform System of Russian Transliteration.

IN NATURE, vol. xli. pp. 396–97, which has only now reached Tashkend, there is a very interesting note under the above title. It is stated that "the recommended system will be adopted without delay." How is this to be understood? Does it mean that the system is finally settled? It would be a pity if this were so, because the proposed method of transliteration contains a point which would be a source of perplexing difficulties when used in practice.

The suppression of the semi-vowels ъ and ь (hard and soft pronunciation) at the ends of words, would make many of them indistinguishable. For instance, with the proposed system, the words

	пыль (dust)	would be	= *puil*
and	пылъ (heat)	,,	= *puil*
	билъ (did heat)	,,	= *bil*
and	биль (a bill)		= *bil*
	яръ (precipice)		= *yar*
and	ярь (verdigris)		= *yar*
	данъ (given)		= *dan*
and	дань (tribute)		= *dzn*

and so on.

The differences of these sounds exist for some purpose in the Russian language, and they ought to be rendered in some way in the transliteration. Perhaps the simplest plan would be to adopt the Polish method of denoting the soft pronunciation with an *accent* above the letter in question. The words just given would then be written *dan* and *dań*, *yar* and *yaŕ*, &c.

I may be allowed to make some further suggestions. They are of minor importance, but would tend to improve, in my opinion, the proposed system.

Would it not be more convenient to transliterate the Russian ы with *y*, as is done in the Polish language? The proposed symbol *ui* does not even remotely represent the right sound, and

may cause numerous cases of confusion with the very similar transliterations of the Russian sounds *yu* and *yй*. Moreover, English readers are already accustomed to render ы with *y*, as, for instance, in the name of the Pribylow Islands. Why should this name be changed now to *Pribuilow*, which is at the same time unfamiliar and misleading? If the change is made, ѣ, ю, я, must be written as *ie, iu, ia*.

The Russian ж might perhaps be better represented by *jh*. The symbol would then represent a softened *j*, equivalent to the French *j*, and reproduce the right sound. A. Wilkins.

Tashkend, April 2/14, 1890.

I assume that the following three conditions must be fulfilled:—

(1) The object aimed at is *principally transliteration*, combined with the possibility of recovering, by its means, the original Russian spelling.

(2) Correct *pronunciation* is only a secondary object, as oral teaching alone can convey it in perfection. Nevertheless, the transliteration adopted should come as near the correct pronunciation as possible, without sacrificing the principal object, transliteration.

(3) The system adopted should satisfy a want, not only of the English-speaking nations, but also, as far as possible, of all those which use the Latin alphabet. This object can be reached only by some mutual concessions.

Now, the system adopted in the article in Nature (vol. xli. p. 397) would, it seems to me, fulfil these requirements as nearly as possible, if the following comparatively slight modifications were admitted:—

(1) The Russian ж would be better rendered by *j* than by *zh*. ж has not quite the same sound as the English *j*, which in most cases has a sound of *d* in it (as in journey, jay, jam). But ж corresponds exactly to the French *j*, and is not too far remote from the German *jet*. For this reason, as a compromise between the three languages, *j*, as an equivalent of ж, would answer better than *zh*. I mean to say that, by means of the *j*, it will be easier for Englishmen, Germans, and Frenchmen to get at the right pronunciation of the Russian ж than through the medium of *zh*.

(2) The Russian ч (*tcha*) should be rendered by *tch* instead of *ch*, and that for the sake of the French and Germans, whose *ch* is pronounced differently from the English *ch*. For the English reader the adoption of either *tch* or *ch* would not involve any difference of pronunciation.

Thus, the Russian *чай* (tea) should be transliterated into *tchaĭ*, which the three nations would pronounce nearly in the same way; whereas, according to the proposed plan, it would be spelt *chaĭ*, which a Frenchman would pronounce *shaĭ* and a German something like *Khaĭ*. Чихачевъ should be spelt *Tchikhatchev*, and not *Chikhachev*.

(3) For a similar reason I would propose *stch* for the Russian щ instead of the *shch* of the proposed system. In Russian сч is pronounced exactly like щ (счастіе, *happiness*, is pronounced щастіе, and счетъ, *an account*, щетъ); and for this reason if ч (*tcha*) is rendered by *tch*, the addition of an *s* would make it щ (*stcha*). The *stch* would be more palatable for the French and Germans than the very puzzling *shch*.

(4) I should propose to use the sign ⁀ for indicating the compound letters—thus, $\widehat{tch}$, $\widehat{stch}$, &c. This would much facilitate the eventual recovery of the Russian letters.

(5) The last letter of the Russian alphabet, ѵ (called *ijitza*), is rendered by *oe* in the table (*loc. cit.*). This must be a misprint.

This letter has become almost obsolete in Russian, and is used in the Church Slavonic only. It is the exact equivalent of the Greek *ypsilon*, and should be rendered by *y*.

The requirements of the Italian pronunciation (with its *c* and *ch*[1]) and of the Spanish (with its *j*) are more difficult to satisfy; but most of the educated Italians and Spaniards understand other languages. Ch. R. Osten-Sacken.

Heidelberg, Germany, May 5.

[1] In De Gubernatis's "Dizionario Biographico," 1879, *Tchikhatchev* is spelt *Cihaceff*.

The Eruption of Vulcano Island.

In the pages of Nature two notes have appeared from my pen describing the phenomena of the eruption that commenced on August 3, 1888, which *apparently* is now coming to an end. I have not been able to visit the spot recently, but my friend and pupil Mr. Lewis Sambon, who helped me in conducting the party of English geologists through the Lipari Islands last autumn, and on whom I can thoroughly depend, has given me the information that I make use of in these notes. Mr. J. P. Iddings, whom Mr. L. Sambon accompanied, also kindly confirmed some of the latter, besides which Mr. Sambon brought back a few very good whole-plate negatives.

From September 1889, when I and the geologists were at Vulcano, the eruption has continued with very varying activity. On March 15, 1890, at 9 p.m., there was a very violent explosion resembling the blowing up of a mine. Some windows were broken at Lipari, which is about seven kilometres distant, whilst lapilli reaching the size of large peas, with drops of condensed vapour, were showered upon the town. Behind Monte della Guardia, which hides Vulcano from the town of Lipari, for upwards of three minutes a bright red reflection was seen, which is of importance as indicating the presence of incandescent matter in the volcanic chimney; for there are floating about a number of extraordinary hypotheses, some verging on the magical, to explain this eruption.

After the evening of the 15th, Vulcano was very active, but the explosions were gradually diminishing in force, and completely stopped on the 17th.

On March 25 my two friends visited the island. They found at the base of the cone an enormous number of the *bread-crust bombs*, the mode of formation of which I have already described and explained. These were of recent ejection, and Mr. L. Sambon says they much resemble those of the earlier period of the eruption; and the specimens which have been kindly brought to me thoroughly confirm this view. Both those examined on the island, and the smaller ones I received still contain numerous fragments of dolerite, which, as I have shown, give origin to much of the pyroxenes, magnetite, olivine, and triclinic felspar distributed throughout the paste, and the origin of which is proved by the fact that they are rarely without a bit of the old microlitic dolerite base still attached to them even when very small crystals nearly isolated occur. Such is the amount of impurity of the paste that any attempt at a chemical analysis would be a waste of time, and even the microscope can afford us little information as to the group of rocks to which the magma belongs. The general facies of the projectiles, the earlier products of this cone, all point to the rock being near to if not really a rhyolitic obsidian. Referring to a discovery I made last autumn Mr. Sambon says:—"I broke a great number of the bombs, but I found in none of them that white agglomeration of quartz and felspar that we often met with in September 1889." These inclusions much resemble numerous similar ones that I found in 1887 in an old lava stream of Stromboli, and which have been sliced, and the examination of which will be published soon. In the meantime they may be said to be composed chiefly of milky quartz and felspar of metamorphic or plutonic origin, and are no doubt the remnants of the sub-volcanic platform.

Some of the recent bombs reach gigantic sizes for such a small volcano. One of these, possibly shot out on March 15, 1890, was, above ground, 9 feet high, 6 feet broad, and 6 feet thick. The obsidian crust was 4 inches thick, and the main fissure, through which the pumiceous interior protruded, was 2 feet broad, forming, as it were, a monster crusty loaf.

So violent were the explosions on March 15, 1889, that Signor Jacono, Mr. Narlian's factor, had to fly for protection with his family to the caves near the Faraglioni, because great stones were falling in considerable numbers near Mr. Narlian's villa, which is about a kilometre from the crater.

Mr. L. Sambon describes the crater as some metres deeper than when we visited it together six months before; but, comparing his and my photographs, there has been very little change. The crater walls were covered with yellow sublimations, which were not so in September 1889, and he judges their inclination at from 40° to 45°. In the centre of the small floor was a great white patch with yellow border, which my experience would lead me to suppose to be due to boric acid, with the edges of a mixture of seleno-sulphur and realgar. A good deal of smoke (which is again new) was issuing from the bottom, especially to the north-north-east; and a few metres only from the edge of the slope beneath the highest point, and extending to where we took our photographs, were a considerable number of fumaroles. One of those nearer the last point (north-north-west) was much larger, issuing from a fissure, and so violent and

menacing as to resemble the old *Caputo*. All of them were roaring, and emitting white fumes.

The fumaroles of the outer rim, including *Caputo*, were very active. These latter worked continuously, whilst the new one on the inner edge would stop and start afresh—a phenomenon I have occasionally seen at Vesuvius, in fumaroles which are in direct communication with the lava. The intermittence, then, seems to be due to the surging up of the lava so as to block from time to time the lower inlet, or to be in other cases dependent upon the bursting of the great vapour bubbles as they rise in the viscous paste.

If this is really the termination of the eruption, we have gained some considerable advance in the interpretation of the eruptive phenomena of a highly acid magma, which is of such feeble character as to be incapable on the one hand of producing a typical pumice, and on the other of giving rise to an outflow of lava. As before stated, differences of opinion will probably be raised as to the nature of the *essential* ejectamenta, and I have little doubt that it will be dubbed as being more basic than it really is in consequence of the presence of impurities of olivine, augite, &c. It may be wise, therefore, that the reasons that lead me to conclude its acid nature should be given. First and foremost, we have the intense viscosity indicated by the long intervals of the explosions and the *bread-crust structure* in the ejectamenta. Secondly, these *bread-crust bombs* I have only met with in the ejectamenta accompanying either rhyolitic or trachytic glassy eruption, such as the obsidians of Rocche Rosse, Forgia Vecchia in Lipari, and Monte Rotaro in Ischia. In the former locality we have a beautiful illustration of the formation of these bombs outside the crater. Towards the end of the Rocche Rosse explosive stage, during which the great crater was drilled and the white pumice erupted, a large mass of obsidian was hurled up, and fell on the crater edge at Monte Pelato. In consequence of the sudden shock on reaching the ground, the semi-plastic mass cracked, and each fragment, relieved from the surrounding pressure, expanded into a small *bread-crust bomb*.

In the third place, the glass of these Vulcano bombs is exceedingly light and transparent, and indicates anything rather than an abundance of any basic iron silicate.

On looking back through the records of fairly well described eruptions, I cannot resist the impression that the duration of an eruption, other proportions being maintained, is in direct ratio to the basicity of the magma which in fact brings about such a result in consequence of the higher viscosity as the proportion of SiO_2 increases. Of course more or less advanced crystallization will also have an influence, as well as the relative higher or lower temperature, in eruptions of pure glass, beside the greater or less abundance of dissolved water.

The appearance of so many new fumaroles which we did not see six months ago all indicates that Vulcano tends (provided there are no more active signs) to pass into a solfataric stage such as is its usual state.

In fine, I must thank Mr. L. Sambon, for so kindly observing carefully the phenomena at Vulcano and transmitting to me his notes, and also Mr. J. P. Iddings for information on the same subject. H. J. JOHNSTON-LAVIS.

Naples, April 18.

Panmixia.

I AM glad to observe that his private correspondence has led Prof. Lankester to regard the doctrine of "panmixia," or "cessation of selection," in a much more favourable light than heretofore.

The form in which I stated this doctrine in 1874, and again in the present correspondence, is the form in which it has likewise been stated by Mr. Galton in 1875, by Prof. Weismann in several of his essays during the past decade, and by Mr. Poulton in his recent lectures. But, speaking for myself, I can see no objection to the form in which it is now presented by Prof. Lankester. For it seems to me immaterial whether we say that panmixia leads to a degeneration of size, shape, or structure, because the previously sustaining power of selection has been withdrawn; or whether we proceed to say that the reason why selection *has* a sustaining power is because, so long as it continues operative, its operation consists in eliminating variations below the standard of full efficiency. But although it appears to me that the latter point goes without saying, if its expression changes the whole aspect of the case in the view of Prof. Lankester, I can only regret that I did not express it in the first instance. I did not, however, understand that there was any question touching the fact of variations occurring below the standard of full efficiency, even as regards fully-developed organs of "well-established species." Therefore my argument was directed to show that, upon the "assumption" of such variability, under cessation of selection the standard will not rise *above* the previous "selection-mean," but always tend to fall *below* it, on account of reversion, &c.

Obviously, however, if we disallow that selection has any sustaining power, the doctrine of degeneration as due to its cessation becomes "absurd." Or, which is the same thing, if we "eliminate altogether" the "assumption" of congenital variations occurring below the standard of full efficiency (when once the parts in question have been completely developed by natural selection), and if we substitute a logically "*possible*" denial of such variations in respect of such parts by "assuming the ratio of birth-mean and selection-mean to be one of equality"—then, indeed, "the point of interest shifts." But surely the burden of proof lies on the side of anyone who denies this variability to fully-evolved organs. Even in the case of "well-established species" it *is* "improbable that there is identity between these two means"—or, in other words, that when once an organ has been fully *evolved* by natural selection, it no longer requires to be *maintained* by natural selection.

Again, "that some cases must occur in which the selection-mean-size is [actually] *smaller* than the birth-mean-size," appears to me true only of cases in which selection has been *reversed*—as, for instance, in flightless insects of oceanic islands. In such cases natural selection is actively engaged in pulling down its previous work. If natural selection be then withdrawn altogether, the adult-mean-size will probably increase. For not only will there now be no reversal of selection, but cessation of the *newer* selection will enable atavism in some measure to re-establish the state of matters which previously existed under the *older* selection. Such, at any rate, are the only cases in which I can imagine even the abstract "possibility" of the cessation of selection leading to an *increase* in size.

In short, the cessation of selection must always produce the opposite results to those which were produced by the selection which has ceased—unless, of course, there be any cases in which there is an "identity between the birth-mean and the selection-mean" (*i.e.* an absence of specific mutability). But even as regards such cases, if they are "assumed" to occur, the assumption amounts to a begging of the question by supposing that the selection has *already* ceased, and ceased when the parts had reached the point of their *maximum* development—an assumption which requires to deny any further mutability in respect of such parts, and therefore seems to me well-nigh incredible. Nevertheless, I fully allow that the more "well-established"—*i.e.* the *less variable*—a species, the smaller will be the necessity for the maintaining power of selection, and hence the smaller effect will result from its withdrawal. This, indeed, we see to be the case even in our domesticated animals—the "inflexible" goose, for instance, having suffered less change at the hands of panmixia than any of our other farm-yard animals.[1]

[1] Nearly all our other domesticated animals yield abundant proof of the potency of panmixia (witness the care with which "methodical selection" is practised on the progeny of pedigree strains), and if we distrust the analogy between artificial and natural selection in this case, we seem to be rather aiming a blow at the principal evidence of the whole Darwinian theory. But as panmixia must act *more rapidly*, and *more completely*, in the case of such newly-acquired products of heredity than it is likely to act in wild species, I agree that experiments ought to be tried upon the latter. Moreover, I fully accept the distinction which Prof. Lankester has drawn in his letter of the 1st inst. between "size" and "structure." But I may remark that the effect of this distinction is not to indicate that panmixia will have no power to reduce size, while it is capable of entirely abolishing structure. What it does indicate is, that because there are greater potentialities of variation in the case of "complex" structures than in the case of mere "bulk," the sustaining power of natural selection is of correspondingly more importance: hence the cessation of selection will lead to the disintegration of structure *more rapidly* and *more completely* than it will to the reduction of bulk—as I have already pointed out elsewhere in relation to the eyeless peduncles of dark-cave Crustacea. Touching other minor points, I may further remark that while in his earlier letters Prof. Lankester accepted Darwin's view that parts are highly variable when selection is withdrawn, in his letter of May 1 he says it is "incontrovertible" that the "only effect" of such withdrawal must be to increase the number of individuals near the average mean—*i.e.* that panmixia both *permits* and *prevents* variability. Again, with regard to what he says about there being no proof that the economy of growth is absent in highly-fed domesticated animals, see Darwin, "Variation," &c.

"cause," see Mill, "Logic," vol. i. pp. 53 and 378 *et seq.*, where the popular *abuse* of both these terms is shown to be exactly that which I have avoided.

Upon the whole, however, we have ended by reaching a much more satisfactory state of agreement than seemed possible when we began. For Prof. Lankester now says he deems it "certain that some cases must sometimes occur in which the selection-mean is larger than the birth-mean," and that as regards such cases I have his "full concurrence in stating that the cessation of selection leads to dwindling." And as he previously agreed that cessation of selection leads also to a loss of shape and disintegration of structure, the only question that remains between us is as to whether there are any cases in which completely developed organs cease to present variations of size below the standard of full efficiency, and therefore will remain unaffected by the withdrawal of the selection by which they were evolved. But this is a question which does not vitally affect the *principle* of panmixia; and it only remains to add that I do fully "reciprocate" what he has said as to there being "no ill-feeling between us."

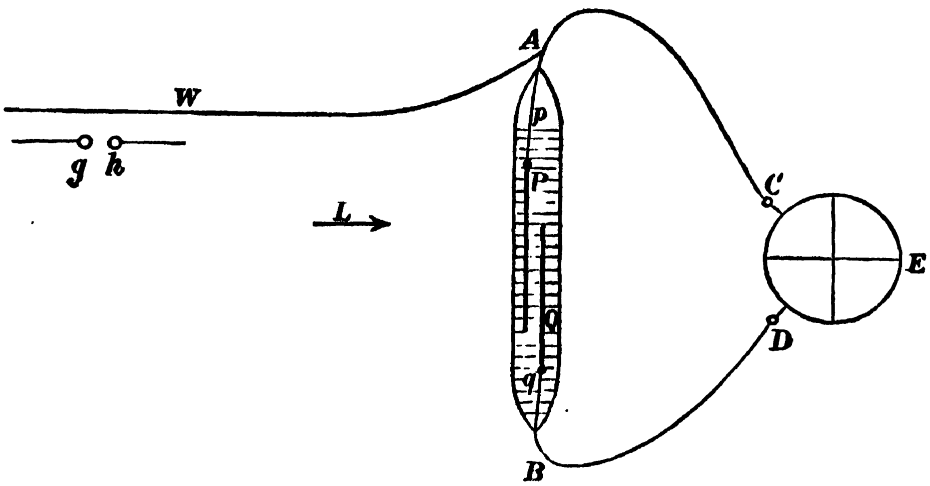
GEORGE J. ROMANES.

Photo-electric Impulsion Cells.

BEFORE publishing in detail the results of many experiments on the generation of electricity by the action of light falling on certain sensitive substances, I wish to make known a result which seems to be of a most remarkable character.

In this communication I shall give merely enough information to enable a reader to understand the special result which I desire now to make known.

The photo-electric cell which I employ consists of a small glass tube, represented in the figure, filled with an alcohol; two metallic plates, P and Q, are immersed in the liquid; each plate is connected with a platinum wire which may either be *soldered to the plate* or passed through a small hole in the plate and *pinched tightly to it*; these wires pass through the ends of the glass tube and are sealed into it. The poles of the cell are A, B, and these are connected with the poles of a quadrant electrometer (Clifton's form of Thomson's).



The plate P is sensitized by a peculiar process, the mere publication of the details of which would not enable a reader to make it successfully. The publication of the process is therefore reserved for a future occasion. The plate Q is quite clean—not sensitized to light. The cell is fixed vertically in a clamp (not represented in the figure). When the cell is of the "impulsion" kind, what happens is as follows. Daylight (represented by the arrow L) being allowed to fall on the sensitive plate P, the spot on the scale of the electrometer moves, and after a few seconds comes to rest, indicating an electromotive force varying with the intensity of the light, its amount for such diffused daylight as we have at present (May 10) at noon being between $\frac{1}{2}$ a volt and $\frac{3}{4}$ of a volt—which is, I submit, a surprisingly great magnitude. On the withdrawal of the light, the deflection falls, and there are means of rapidly getting rid of the deflection without injury to the cell. Either before or after this deflection caused by light ceases, let a slight tap (sometimes inaudible) be given to the base or clamp in which the cell rests, and then results a remarkable change in the cell. *It is no longer sensitive to light.* This insensitive state is indicated by a rapid return motion of the spot on the scale; it is merely *indicated* by this motion, there being no necessary connection between this motion and the insensitive state, for if the cell were now left for some time (perhaps an hour or so) in the dark, the disturbing E.M.F. of the cell would vanish, and there would be nothing to tell us that the cell remains insensitive; but that it is really still in the insensitive state we find at once on again exposing it to light. Another gentle tap given to the clamp, or the stone table on which the whole apparatus rests, will restore the sensitive state; and so on indefinitely, the sensitive and insensitive states following each other and being produced, in the case of many such cells, with great ease.

These results I found a long time ago, and they have been seen by or communicated to several scientific friends. From the first, I maintained that the results are due to an alteration of the molecular state of the sensitive surface, or of the layer of contact of this surface with the liquid, and that in one arrangement of the molecules the light energy can be taken up electrically, while it cannot be so taken up in the other. In my first experiments the plates were tightly pinched to the platinum wires—not soldered, as soldering endangered the sensitive layer—and the obvious objection was made that "loose contacts" were unsatisfactory. I have several results, however, which dispose of this objection even in the case of very loose contacts; but I may set the matter at rest by saying that I have been able to make soldered junctions, and with them to obtain the results.

I now come to the special point which is the occasion of this communication. A few days ago I was investigating the effect of static charges communicated to the plates on the sensitive and insensitive states, and in the course of these experiments I found that if a Voss machine, not in any way connected with the cell or the electrometer, was worked in the room while the cell was in the insensitive state, *the moment a spark passed between the poles of the Voss, the insensitive state was altered to the sensitive*, whether the cell was connected with the electrometer or not. Finally, I found that the best method of showing the inductive effect of the spark is to connect an insulated wire, W, apparently of any length, to either pole (A in the figure) of the cell, and to place the poles, *g*, *h*, of the Voss near the wire (a distance of several feet will do with a spark about half an inch long). If *g* and *h* are two or three feet from any part of the wire W, a spark about one-eighth of an inch long suffices to change the cell from the insensitive to the sensitive state.

The effect is not one on the electrometer, nor is it due to sound, and I have repeated the results with several cells many scores of times before people interested in them. At present I am endeavouring to produce by *electro-magnetic induction* the reverse change, viz. that from the sensitive to the insensitive state; but, although such must apparently be possible, I have not yet succeeded.

The sudden alteration of the insensitive to the sensitive state is produced in a most marked manner by the spark of a Hertz oscillator at as great a distance as the laboratory room in which I work allows. This distance is usually only about eight or ten feet, but I observed the change effected occasionally when the oscillator was at a distance of some thirty feet or more. In this latter case, however, the action was interfered with by the unavoidable presence of wires along the walls, &c., intervening between the Hertz and my impulsion cell.

If the cause to which I have assigned the change from the photo-electrically insensitive to the photo-electrically sensitive state of the cell is the true one, it is impossible to avoid the speculation that impulsion results of this kind may be very common in the economy of Nature; and that the mode in which solar energy is taken up by plants may be affected, and even altered in kind, by sudden electro-magnetic disturbances. The effect of a Hertz oscillation is, indeed, not confined to an alteration of a plate from the insensitive to the sensitive state; for I have cells in which if the sensitive plate is, on exposure to light, electrically negative to the back plate, a Hertz oscillator at a distance will reverse the relation when the plate is again exposed to light.

GEORGE M. MINCHIN.

Royal Indian Engineering College, Cooper's Hill,
May 10.

P.S.—While the above communication was going through the press, I made an experiment which renders it almost certain that in the impulsion cells the results are due to the formation of some

oscillating layer at the surface of the sensitive plate. Being anxious to keep the alcohol in the cell (which in this instance was closed by a ground glass cap), I sealed the cell into a glass tube through the extremities of which the wires of the cell passed. The effect of the disturbance thus resulting was that no amount of tapping the support of the cell would change it from the sensitive to the insensitive state, although before being thus treated it was sensitive to the most minute disturbance. I suspected, however, that after some hours the liquid and the plate would again enter into the peculiar relation on which the impulsion results depend, and so it turned out—after three hours the cell could be rendered insensitive by taps and sensitive by the inductive effect of a Voss machine. The platinum wires were *soldered* to the plates. I see that the distances at which I found the Hertz oscillator effective in influencing the cells were greater than those above stated; but I have not been able to renew work with the oscillator, which belongs to Mr. Gregory, who removed it for exhibition at the Royal Society's meeting.

May 16.

Bison not Aurochs.

I AM glad that Mr. Lydekker accedes (NATURE, May 15, p. 53) to the correction of which I had pointed out the need. But the "vulgar error"—if the Editor will allow me to use a phrase made classical nearly 250 years ago by Sir Thomas Browne—is of more ancient date than my friend seems to suppose; and Dr. Gadow has kindly referred me to Prof. Wrześniowski's "Studien zur Geschichte des polnischen Tur," published in May 1878 (*Zeitschr. für wissenschaftl. Zoologie*, xxx. pp. 493-555). Therein will be seen reduced copies of the engravings in an edition of Herberstein's "Rerum Moscoviticarum Commentarii" (Basileæ: 1571), giving a figure of each of the animals. The first is inscribed

> VRVS SVM, POLONIS TVR, GERMANIS AVROX:
> IGNARI BISONTIS NOMEN DEDERANT.

Over the second may be read

> BISONS SVM, POLONIS SVBER, GERMANIS BISONT: IGNARI VRI NOMEN DEDERANT.

This paper is well worth reading from the amount of curious information to be found in it. I have been able to consult only one copy of this work, of an earlier edition indeed, for it was published at Antwerp in 1557; but it does not contain these figures, though the passages quoted by the Polish Professor of course occur (*ff.* 117 *verso et seqq.*). The figures are not remarkable for beauty, and if anyone were to call them caricatures I should hardly complain; but they are certainly of interest, and that of the Urus, which I think I have seen copied elsewhere, is perhaps the only approach to an original representation extant. If so it deserves to be better known. Allow me to remark that this is not the first time that I have noticed this error. I did so many years ago in a little pamphlet "On the Zoology of Ancient Europe" (p. 14), published by Messrs. Macmillan in 1862; and I may add that any visitor to the Museum of Zoology of this University may see therein a skeleton of the Aurochs and of the Bison, as well as of the American "Buffalo"—all standing side by side. ALFRED NEWTON.

Magdalene College, Cambridge, May 18.

Sudden Rises of Temperature.

IN NATURE, vol. xli. p. 559, it is stated that sudden rises of temperature of large amount in Great Britain "are more frequent and more extensive in amount than sudden falls—the reverse to what obtains in India." There appears to be a somewhat similar condition of affairs in North America. Extremely sudden and large rises of temperature attend the warm Chinook winds, as they are called, which occur over the western part of the continent, but are unknown further east. Equally pronounced are the sudden falls of temperature in the eastern half of the country popularly termed "cold waves." M. A. VEEDER.

Lyons, N.Y., May 7.

Coral Reefs, Fossil and Recent.

IN Dr. von Lendenfeld's communication to NATURE of May 8 (p. 30), occurs the following:—

"Dr. Murray goes on to say . . . and an isolated atoll rising precipitously, perhaps 10,000 feet from the sea-bottom, will be formed." And again—"and far less will it enable an atoll rising 10,000 feet or more from the bottom of the sea . . ."

I cannot think that the author quoted has committed himself to any such figures as these, but if either he or Dr. von Lendenfeld can tell me where to find such a formation in existing seas, I shall be obliged; as I have sought in vain for instances yet known of any slopes that could be called "*steep*" descending to more than 4000 feet or so, while *precipitous* slopes are unknown to me beyond 1200 feet; and these are, so far as I know, very exceptional.

While I am writing on this subject, I should be glad if anyone would explain how, on the assumption that atolls are formed during subsidence, it comes about that, while the outer slopes descend to great depths, the depth of the largest lagoons inclosed is generally confined to about 45 fathoms, and in one or two cases to 60 fathoms, but is never more. Why should not the lagoon of an atoll twenty or thirty miles in diameter, which rises steeply from depths of 200 or 300 fathoms or more, have a depth of at any rate 100 fathoms, allowing for the most extravagant amount of silt from the *débris* of the rim.

W. J. L. WHARTON.

Doppler's Principle.

A COMPLETE solution of the questions about which your correspondents are puzzling themselves has been before the public for some ten years in several successive editions of my "Deschanel." It occurs in the last paragraph of the chapter entitled "Numerical Evaluation of Sound," and is as follows:—

"Let the source make n vibrations per second. Let the observer move towards the source with velocity a. Let the source move away from the observer with velocity a'. Let the medium move from the observer towards the source with velocity m, and let the velocity of sound in the medium be v.

"Then the velocity of the observer relative to the medium is $a - m$ towards the source, and the velocity of the source relative to the medium is $a' - m$ away from the observer. The velocity of the sound relative to the source will be different in different directions, its greatest amount being $v + a' - m$ towards the observer, and its least being $v - a' + m$ away from the observer. The length of a wave will vary with direction, being $\frac{1}{n}$ of the velocity of the sound relative to the source. The length of those waves which meet the observer will be $\frac{v + a' - m}{n}$ and the velocity of these waves relative to the observer will be $v + a - m$; hence the number of waves that meet him in a second will be $\frac{v + a - m}{v + a' - m} n$."

The three quantities a, a', m may of course be either positive or negative. J. D. EVERETT.

5 Princess Gardens, Belfast, May 17.

THE SHAPES OF LEAVES AND COTYLEDONS.[1]

ATTEMPTS to explain the forms, colours, and other characteristics of animals and plants, though not new, were until recent years far from successful. Our Teutonic forefathers had a pretty story which explained certain characteristics of several common plants.

Balder, the God of Mirth and Merriment, was, characteristically enough, regarded as deficient in the possession of immortality. The other divinities, fearing to lose him, petitioned Thor to make him immortal, and the prayer was granted on condition that every animal and plant would swear not to injure him. To secure this object, Nanna, Balder's wife, descended upon the earth. Loki, the God of Envy, attended her disguised as a crow (crows at that time were white), and settled on a little blue flower, hoping to cover it up so that she might overlook it. The flower, however, cried out "Forget-me-not, forget-me-not" (and has ever since been known under that name). Loki then flew up into an oak and sat on a mistletoe. Here he was more successful. Nanna carried off the

[1] Lecture delivered at the Royal Institution on April 25, by Sir John Lubbock, Bart., M.P., D.C.L., F.R.S., &c.

oath of the oak, but overlooked the mistletoe. She thought, however, and the divinities thought, that she had successfully accomplished her mission, and that Balder had received the gift of immortality.

One day, thinking Balder proof, they amused themselves by shooting at him, posting him against a holly. Loki tipped an arrow with a piece of mistletoe, against which Balder was not proof. This unfortunately pierced him to the heart, and he fell dead. Some drops of his blood dropped on the holly, which accounts for the redness of the berries; the mistletoe was so grieved that she has ever since borne fruit like tears, and the crow, whose form Loki had taken, and which till then had been white, was turned black.

This pretty myth accounts for several things, but is open to fatal objections. You will judge whether I am more fortunate. In the first place I need hardly observe that the forms of leaves are almost infinitely varied. To quote Ruskin's vivid words, they "take all kinds of strange shapes, as if to invite us to examine them. Star-shaped, heart-shaped, spear-shaped, arrow-shaped, fretted, fringed, cleft, furrowed, serrated, sinuated, in whorls, in tufts, in spires, in wreaths, endlessly expressive, deceptive, fantastic, never the same from footstalk to blossom, they seem perpetually to tempt our watchfulness, and take delight in outstripping our wonder."

Now, why is this marvellous variety, this inexhaustible treasury of beautiful forms? Does it result from some innate tendency of each species? Is it intentionally designed to delight the eye of man? Or has the form and size and texture some reference to the structure and organization, the habits and requirements, of the whole plant?

The leaf, although so thin, is no mere membrane, but is built up of many layers of cells, and the interior communicates with the external air by millions of little mouths, called stomata, which are generally situated on the under side of the leaf. The structure of leaves varies as much as their forms.

It is, of course, principally in hot and dry countries that leaves require protection from too much evaporation.

The surface is in some cases protected by a covering of varnish, in others by saline or calcareous excretions. In others, again, the same object is attained by increased viscidity of the sap; in some, the leaves assume a vertical position, thus presenting a smaller surface to the rays of the sun. In other cases the leaves become fleshy. Woolly hairs are also a common and effective mode of protection. The plants of deserts are very frequently covered with a thick felt of hair. Some species, again, which are smooth in the north tend to become woolly in the south. Species of the cool spring again tend to be glabrous. The uses of hairs to plants are indeed very various. They serve, as just mentioned, to check too rapid evaporation. They form a protection for the stomata or breathing holes, and consequently, as these are mainly on the under side of leaves, we find that when one side of the leaf is covered with white felted hairs, as the white poplar, this is always the under size.

In other cases the use of hair is to throw off water. In some Alpine and marsh plants this is important. If the breathing holes became clogged with moisture—with fog, for instance, or dew—they would be unable to fulfil their functions. The covering of hair, however, throws off the moisture, and thus keeps them dry. Thus these hairs form a protection both against too much drought, and too much moisture.

Another function of hairs which cannot be omitted is to serve as shades against too brilliant light, and too much heat. Again, hairs serve as a protection against insects, and even against larger animals. The stinging hairs of the common nettle are a familiar example, and coarse woolly hairs are often distasteful to herbivorous quadrupeds.

Deciduous leaves especially characterize the comparatively cool and moist atmosphere of temperate regions. For different reasons evergreen leaves become more numerous in the Alps and in the tropics.

In the Alps it is necessary for plants to make the most of the short summer. Hence, perennial and evergreen species are more numerous in proportion than with us. Everybody must have noticed how our trees are broken if we have snow early in the season and when they are still in leaf.

The comparatively tough and leathery leaves, such as those of the evergreen oak and olive, are protected against animals by their texture, and often, as in the holly, by spines; they are better able to resist the heat and dryness of the south than the comparatively tender leaves of our deciduous trees, which would part too rapidly with their moisture. It is perhaps an advantage to evergreen leaves to be glossy, because it enables them better to throw off snow. Moreover, their stomata are often placed in pits, and protected with hair, which prevents too rapid evaporation. The texture and structure of leaves is indeed a wide and very interesting subject, but to-night I must confine myself to the shape.

It is impossible to classify plants by the form of the leaf, which often differs greatly in very nearly allied species. Thus the common plantain of our lawn (*Plantago major*) has broad leaves, *P. lanceolata* narrow ones. The width or narrowness of leaves depends on various considerations. In herbaceous and stalkless plants, such as the plantain, prostrate leaves tend to be broad, those which are upright to be narrow. Thus, grasses, for instance, have more or less upright narrow leaves.

In other cases the width is determined by the distance between the buds, and in others again by the number of leaves in a whorl.

Cordate and Lobed Leaves.

Among broad leaves we may observe two distinct types, according as they are oval or palmate. Monocotyledonous plants, such as grasses, sedges, lilies, hyacinths, very generally have upright and narrow leaves. When they are wider, as, for instance, in the black bryony, this is mainly at the base, where, consequently, the veins are further apart, coming together again towards the apex. This we are tempted therefore to regard as the primitive type of a broad leaf.

There is, however, a totally different one, where the leaf is palmate, like a hand, widening towards the free end. Here the veins pursue a straight, diverging course and as they not only serve to strengthen the leaf, but also to carry the nourishment, this is doubtless an advantage. Another reason perhaps for this arrangement is found in the fact that these leaves are generally folded up, like a fan, while they are in the bud.

I have elsewhere dwelt on the case of the beech, and perhaps I may briefly refer to it again. The weight of leaves which a branch can carry will of course depend on its position and strength. The mode of growth of the beech and the hornbeam are very similar, but the twigs of the latter are slenderer, and the leaves smaller. If we cut off a beech branch below the sixth leaf we shall find that the superficial leaf area which it carries is about 18 square inches. But in our climate most leaves are glad of as much sunshine as they can secure, and are arranged with reference to it. The width of the beech leaves, about $1\frac{3}{4}$ inch, is regulated by the average distance between the buds. If the leaves were wider they would overlap. If they were narrower there would be a waste of space. The area on the one hand, and the width on the other, being thus determined, the length is fixed, because, to secure an area of 18 inches, the width being about $1\frac{3}{4}$ inch, the length must be about 2 inches. This, then, explains the form of the beech leaf.

Let us apply these considerations in other cases. I

will take, for instance, the Spanish chestnut and the black poplar. In the Spanish chestnut the stem is much stronger than that of the beech. Consequently it can carry a greater leaf-surface. But the distance between the buds being about the same the leaves cannot be much wider; hence they are much longer in proportion, and this gives them their peculiar sword-blade-like shape.

Now, if we look at the end of a branch of black poplar and compare it with one of white poplar, we are struck with two things: in the first place, the branch cannot be laid out on a sheet of paper so that the leaves shall not overlap; the leaves are too numerous and large. Secondly, in the white poplar the upper and under surfaces of the leaf are very different, the lower one being covered with a thick felt of hair, which gives it its white colour; in the black poplar, on the other hand, the two surfaces are nearly similar.

These two characteristics are correlated, for while in the white poplar the leaves are horizontal, in the black poplar, on the contrary, they hang vertically. Hence the two surfaces are under very similar conditions, and consequently present a similar structure; while for the same reason they hang free from one another.

Let us again look for a moment at the great group of Conifers. Why, for instance, do some have long leaves and some short ones? This, I believe, depends on the strength of the twigs and the number of years which the leaves last; long leaves dropping after one, two, or three years, while species with shorter ones retained them many years—the spruce fir, for instance, 8 or 10, *Abies Pinsapo* even as many as 18.

[Here Sir John dwelt on and explained the forms of several familiar leaves.]

Seedlings.

I now come to the second part of my lecture—the forms of cotyledons. Anyone who has ever looked at a seedling plant must have been struck by the fact that the first leaves differ entirely from those which follow—not merely from the final form, but even from those which immediately follow. These first leaves are called cotyledons. The forms of many cotyledons have been carefully described, but no reason had been given for the forms assumed, nor any explanation offered why they should differ so much from the subsequent leaves. Klebs, indeed, in his interesting memoir on "Germination," characterizes it as quite an enigma.

Mustard and cress were the delight and wonder of our childhood, but it never then occurred to me at least to ask why they were formed as they are. So they grew, and beyond that it did not occur to me, nor I think to most, that it was possible to inquire. I have, however, I think, suggested plausible reasons in many cases, some of which I will now submit for your consideration. Cotyledons differ greatly in form.

Some are narrow, in illustration of which I may mention the fennel and ferula, in the stalk or ferule of which Prometheus is fabled to have brought down fire from heaven.

Some are broad, as in the beech and mustard. Moreover, some species have narrow cotyledons and broad leaves, while others have broad cotyledons and narrow leaves.

Some are emarginate, as in the mustard; lobed, as in the lime; bifid, as in Eschscholtzia; trifid, as in the cress; or with four long lobes, as in Pterocarya.

Some are unequal, as in the mustard; or unsymmetrical, as in the geranium.

Some are sessile, and some are stalked; some are large, some small.

Generally, they are green, leaf-like, and aërial, but sometimes they are thick and fleshy, as in the oak, nut, walnut, peas, beans, and many others, in which they never quit the seed at all.

Let us see, then, whether we can throw any light on these differences, and why they should be so unlike the true leaves.

If we cut open a seed, we find within it the future plant: sometimes, as in the larkspur, a very small oval body; sometimes, as in the ash, or the castor-oil, a lovely little miniature plant, with a short stout root and two well-formed leaves, inclosing between them the rudiment of the future stem; the whole lying embedded in food-material or perisperm; while sometimes the embryo occupies the whole interior of the seed, the food-material being stored up, not round, but in the seed-leaves or cotyledons themselves. Peas and beans, almonds, nuts, and walnuts are familiar cases. In split peas, for instance,—who split the peas? If you look at them you will see that it is too regularly and beautifully done for human hands. In fact, the two halves are the two fleshy cotyledons: strictly speaking, they are not split, for they never were united.

Narrow Cotyledons.

Let us now begin with such species as have narrow cotyledons, and see if we can throw any light on this characteristic. The problem is simple enough in such cases as the plane, where we have, on the one hand, narrow cotyledons, and, on the other hand, a long narrow seed fully occupied by a straight embryo. Again, in the ash, the cotyledons lie parallel to the longer axis of the seed, which is narrow and elongated. Such cases are, however, comparatively few; and there are a large number of species in which the seeds are broad and even orbicular, while yet the cotyledons are narrow.

In these it will generally be found that the cotyledons lie transversely to the seed.

The sycamore has also narrow cotyledons, but the arrangement is very different. The fruit is winged, the seed somewhat obovoid and aperispermic—that is to say, the embryo, instead of lying embedded in food-material, occupies the whole cavity of the seed. Now, if we wished to pack a leaf into a cavity of this form, it would be found convenient to choose one of a long strap-like shape, and then roll it up into a sort of ball. This is, I believe, the reason why this form of cotyledon is most suitable in the case of the sycamore.

Broad Cotyledons.

I now pass to species with broad cotyledons. In the castor-oil plant, Euonymus, or the apple, for instance, the young plant lies the broad way of the seed, and the cotyledons conform to it. In the genus Coreopsis, *Coreopsis auriculata* has broad cotyledons, and *Coreopsis filifolia* has narrow ones—the first having broad, the second narrow seeds.

In a great many species the cotyledons are emarginate—that is to say, they are more or less deeply notched at the end. This is due to a variety of causes. One of the simplest cases is that of the oak, where the two fleshy cotyledons fill the seed; and as the walls of the seed are somewhat thickened at the end, and project slightly into the hollow of the seed, this causes a corresponding depression in the cotyledons.

In such cases as the mustard, cabbage, and radish, the emargination is due to a very different cause. The seed is oblong, thick, and slightly narrower at one end than the other. There is no perisperm, so that the embryo occupies the whole seed, and as this is somewhat deep, the cotyledons, in order to occupy the whole space, are folded and arranged one over the other like two sheets of note-paper, the radicle being folded along the edge. To this folding the emargination is due. If a piece of paper be taken, folded on itself, cut into the form of the seed, and then unfolded, the reason for the form of the cotyledon becomes clear at once.

But it may be said that in the wallflower the seed has a

similar outline, and yet the cotyledons are not emarginate. The reason of this is that in the wall-flower, Cheiranthus, the seed is more compressed than in the mustard and radish, and consequently the cotyledons are not folded; so that the whole, not the half, of each cotyledon corresponds to the form of the seed.

Lobed Cotyledons.

The great majority of cotyledons are entire, but some are more or less lobed. For instance, those of the mallow are broadly ovate, minutely emarginate, cordate at the base, and three-lobed or angled towards the apex, with three veins, each running into one of the lobes.

The embryo is green, curved, and occupies a great part of the seed. The cotyledons are applied face to face; then, as growth continues, the tip becomes curved and depressed into a median longitudinal furrow, the fold of the one lying in that of the other.

[Sir John then showed clearly by diagrams and paper how the emargination arises, but it cannot be made clear without illustrations.]

The cotyledons of the lime are very peculiar. They are deeply five-lobed, the central lobe being the longest; so that they are roughly shaped like a hand. The seed is an oblate spheroid, resembling an orange in form, and the embryo is embedded in semi-transparent albumen.

The embryo is at first straight; the radicle is stout and obtuse; the cotyledons ovate-obtuse, plano-convex, fleshy, pale green, and applied face to face. They grow, however, considerably, and when they meet the wall of the seed, they bend back on themselves, and then curve round, following the general outline of the seed. If anyone will take a common tea-cup and try to place in it a sheet of paper, the paper will, of course, be thrown into ridges. If these ridges be removed and so much left as will lie smoothly inside the cup, it will be found that the paper has been cut into lobes more or less resembling those of the cotyledons of Tilia. Or if, conversely, a piece of paper be cut into lobes resembling those of the cotyledons, it will be found that the paper will fit the concavity of the cup. The case is almost like that of our own hand, which can be opened and closed conveniently owing to the division of the five fingers.

Unequal Cotyledons.

In most cases the two cotyledons are equal, but there are several cases in which one of them is larger than the other. They had not escaped the attention of Darwin, who attributed the difference to the fact "of a store of nutriment being laid up in some other part, as in the hypocotyl, or one of the cotyledons." I confess that I do not quite see how this affords any explanation of the fact. The suggestion I have thrown out is that the difference is due to the relative position of the two cotyledons in the seed, which in some cases favours one of them at the expense of the other. Thus in the mustard they are unequal, and, as we have already seen, they are folded up, one inside the other. The outer one, therefore, has more space, and becomes larger. In many other Crucifers, though the cotyledons are not folded, they are what is called "incumbent"—that is to say, they are folded on the radicle, and the outer one has therefore more room than the other.

Unsymmetrical Cotyledons.

In other cases, as in the geraniums, laburnum, lupines, &c., there is inequality, not between the two cotyledons, but between the two halves of each cotyledon. In the geraniums this is due to the manner in which the cotyledons are folded. In cabbage and mustard we have seen that one cotyledon is folded inside the other; in the geranium they are convolute, one half of each being folded inside one half of the other, the two inner halves being the smaller, the two outer the larger ones.

In the laburnum, where the arrangement is very similar, the inequality in the two sides of the cotyledon is due to the inequality between the two sides of the seed.

Subterranean Cotyledons.

I have already observed that in some cases the cotyledons occupy the whole of the seed, which, in more or less spherical seeds is effected either by a process of folding and packing, or by the cotyledons becoming themselves more or less thickened, as in peas and beans, nuts and chestnuts. This is the reason why such seeds fall more or less readily into two halves, the radicle or plumule being so small in comparison as generally to escape notice, though, if a horse-chestnut is peeled, the radicle appears as a sort of tail.

In some beans the cotyledons sometimes emerge from the seed, sometimes remain underground. In others, as also in the oak and horse-chestnut, they never leave the seed, or come above ground: they have lost the function of leaves and become mere receptacles of nourishment.

Did it ever occur to you to think, when you have been eating walnuts, why their structure is so complex, and why the edible part is thrown into those complicated lobes and folds? The history is very interesting.

In the walnut, the cotyledons now never leave the seed, but in an allied genus, Pterocarya, they come above ground as usual, and are very peculiar in form, being deeply four-lobed. The reason of this is very curious. The fruit is originally much larger than the seed, but, as it approaches maturity, the hard woody tissue disintegrates at four places, leaving thus four hollow spaces. Into these spaces the seed sends four projections, and into these four projections each cotyledon sends a lobe. Hence the four lobes.

Now in the walnut a very similar process takes place, only the hollow spaces are much larger, so that, instead of a solid wall, with hollow spaces occupied by the seed, it gives the impression as if the seed was thrown into folds occupied by the wall of the fruit. To occupy these spaces fully, the cotyledons themselves were thrown into folds as we now see them. The fruit of Pterocarya is much smaller than that of the horse-chestnut, which doubtless was itself formerly not so large as it now is. As it increased, the cotyledons became fleshier and fleshier, and found it more and more difficult to make their exit from the seed, until at last they have given up any attempt to do so. Hence these curious folds, with which we are so familiar, are the efforts made by the originally leafy cotyledons to occupy the interior of the nut. If you separate them, you will easily find the little rootlet, and the plumule with from five to seven pairs of minute leaves.

But perhaps you will ask me why I have assumed that in these cases the cotyledons have conformed to the seeds? May it not be that the seed is determined, on the contrary, with reference to the cotyledons? The size, form, &c., of the seeds, however, evidently have relation to the habits, conditions, &c., of the parent plant.

Let me, in illustration, take one case. The cotyledons of the sycamore are long, narrow, and strap-like; those of the beech are short, very broad, and fan-like. Both species are aperispermic, the embryo occupying the whole interior of the seed.

Now, in the sycamore, the seed is more or less an oblate spheroid, and the long ribbon-like cotyledons, being rolled up into a ball, fit it closely, the inner cotyledon being often somewhat shorter than the other. On the other hand, the nuts of the beech are more or less triangular: an arrangement like that of the sycamore would therefore be utterly unsuitable, as it would necessarily leave great gaps. The cotyledons, however, are folded up like a fan, but with more complication, and in such a manner that they fit beautifully into the triangular nut.

Can we, however, carry the argument one stage further? Why should the seed of the sycamore be globular, and that of the beech triangular? Is it clear that the cotyledons are constituted so as to suit the seed? May it not be that it is the seed which is adapted to the cotyledons? In answer to this we must examine the fruit, and we shall find that in both cases the cavity of the fruit is approximately spherical. That of the sycamore, however, is comparatively small, say ⅓ inch in diameter, and contains one seed, which exactly conforms to the cavity in which it lies. In the beech, on the contrary, the fruit is at least twice the size, and contains from two to four fruits, which consequently, in order to occupy the space, are compelled (to give a familiar illustration, like the segments of an orange) to take a more or less triangular form.

Thus, then, in these cases, starting with the form of the fruit, we see that it governs that of the seed, and that of the seed, again, determines that of the cotyledons. But though the cotyledons often follow the form of the seed, this is not invariably the case: other factors must also be taken into consideration; but when this is done, we can, I venture to think, throw much light on the varied forms which seedlings assume.

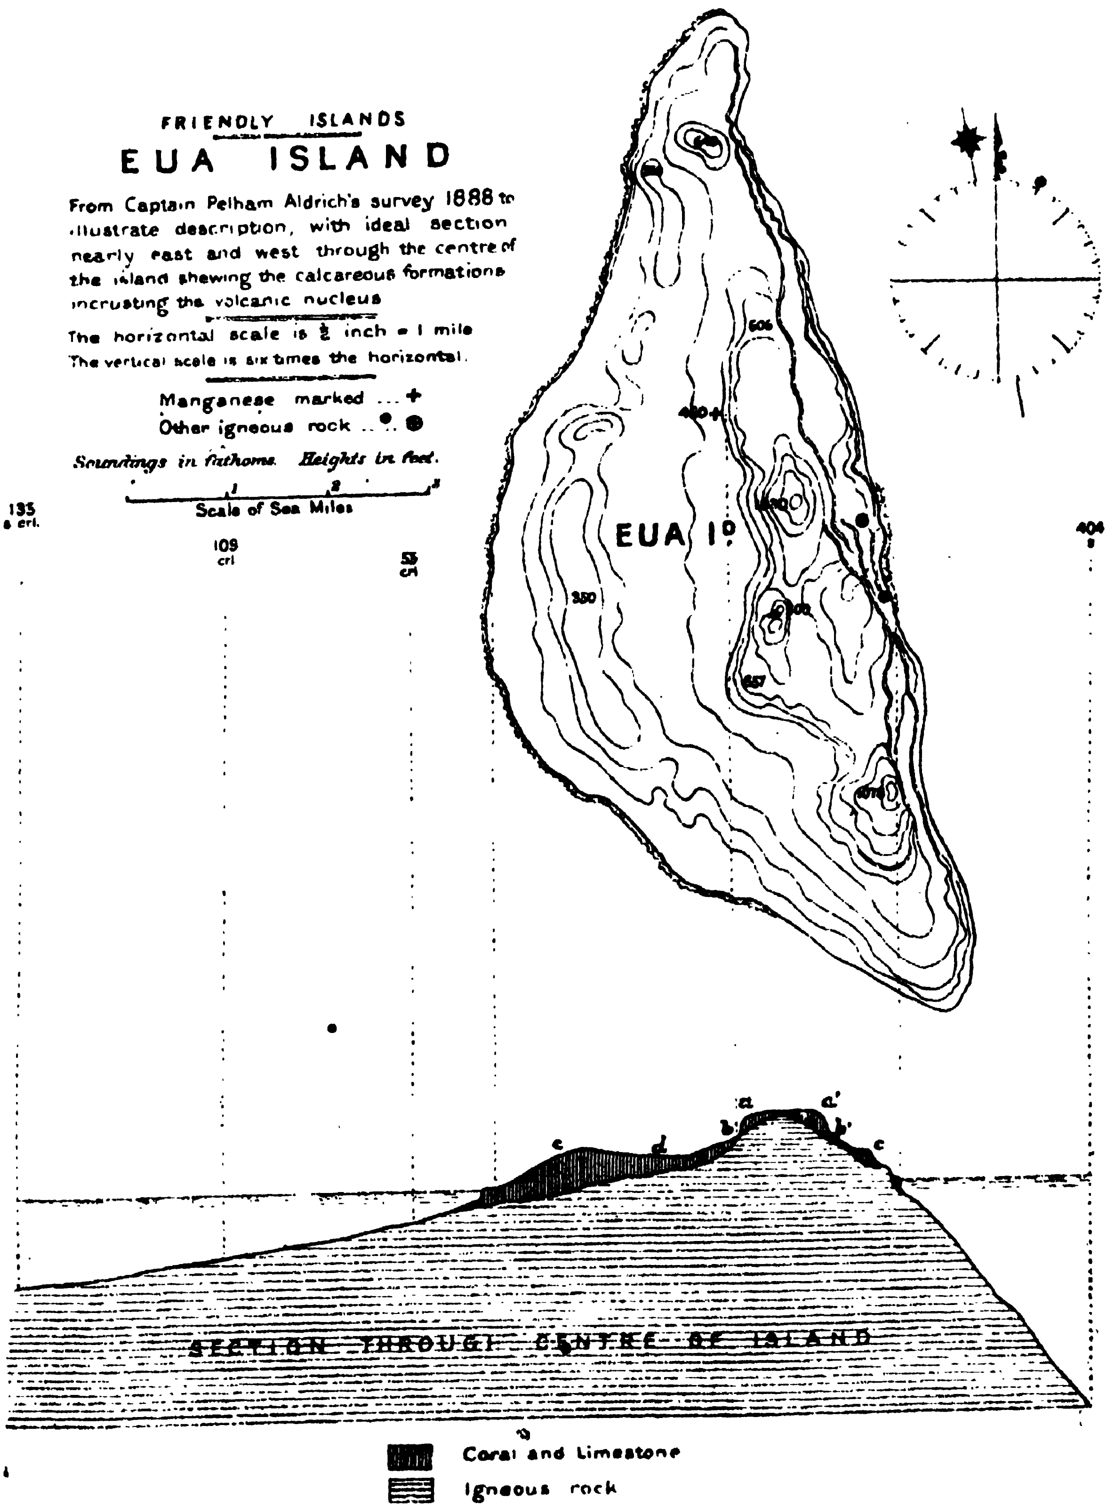
I have thus attempted to indicate some of the principles on which, as it seems to me, the shapes of leaves and seedlings depend, and to apply them in certain cases, but the study is only in its infancy: the number and variety of leaves is almost infinite, and the whole question offers, I venture to think, a very interesting field for observation and research—one, indeed, of the most fascinating in the whole of natural history.

EUA ISLAND, TONGA GROUP.

THE following description of Eua Island (one of the higher members of the Friendly or Tonga Islands, and familiar to readers of "Cook's Voyages" as Middleburgh), written by Commander Oldham, of H.M. surveying-ship *Egeria*, will be of interest to geologists and those interested in the coral controversy.

W. J. L. WHARTON.

"When viewed from the westward, Eua is seen to consist of grassy table-lands and slopes, having clumps of dark-green trees dotted here and there, giving it a park-like appearance. It is formed of two coral terraces resting on a volcanic nucleus. The upper terrace, about 600 feet above the level of the sea, rises to a summit 1030 feet high; the lower terrace attains a height of only 350 feet. On the western side of the island these terraces are separated a distance of from one to one and a half miles, and in some places there is a depression between them; the eastern side is very precipitous, the terraces there being very narrow, and forming cliffs at their seaward edges.



"The upper terrace seems composed of foraminiferous limestone and reef rock, with volcanic rock (a hydrated oxide of manganese) cropping out on the western side at the edge of the terrace where the coral rock has been removed by the effects of weather. The limestone is compact, reddish-brown, and largely foraminiferous. It is both *in situ* and scattered in detached blocks over the upper terrace, and when weathered has a honeycombed appearance.

"Low coral cliffs, which in many places form the shore-line, give indications of recent elevation, being marked by two distinct lines of erosion. On the beach, on the eastern side of the island, I observed that the sea had washed up recently high above the ordinary high-water mark; trunks of cocoa-nuts were lying about rotting, and the lower part of the stems of those still standing near the shore had been washed by salt water. This was afterwards explained by the fact that a very high tide occurred on March 18 (about the time of the hurricane at Samoa), which rose 2 feet above high-water mark, and remained so for fifteen minutes. A narrow fringing reef generally borders the island. On the eastern side of the island, below the summit, at an elevation of 300 feet, volcanic stones were observed lying in the bed of a stream, and on the beach, a little further south, are dykes of volcanic rock; one of diorite shows through the beach, another, which is close-to, is about 100 feet high, and can be traced a short distance inland. The inner part has *coral-reef rock, conformable, superimposed*. The beach for a considerable distance either side is strewn with blocks of conglomerate formed of coral and volcanic rocks cemented together.

"The higher part of the lower terrace on the western side of the island was found to be composed of coral-reef rock.

"The present volcanic nucleus must have been originally below the surface, but sufficiently near to allow coral to grow, and reef-making Foraminifera to be deposited on its summit. It was then evidently elevated about 300 feet (marked *aa'*, *bb'* in section) in a comparatively short interval, after which a long period of rest, or subsidence, followed, during which coral grew (forming the portion *bb'* to *cc'*), and a lagoon (*d*) was produced. Then another period of elevation raised the island to its present height, and exposed the volcanic foundation.

"C. F. OLDHAM."

I am indebted to Captain Wharton for sending me the specimens collected by Commander Oldham. The limestones, some of which are fairly crystalline in character, are composed of Foraminifera and water-worn fragments of calcareous Algæ ("Nullipores"). The deposit of hydrated manganese oxide cropping out from below the limestone is remarkable, but it has all the appearance of an ordinary terrestrial deposit. A much-weathered mass from the neighbourhood contains many beautiful crystals of magnetite. Although the rocks forming the nucleus of the island are of igneous origin, they are not modern volcanic materials. They consist of much altered glassy andesites (porphyrites) with epidiorites; and are suggestive of ancient volcanic masses that have been exposed at the surface by denudation. The significance of such facts as these has been pointed out by Prof. Bonney and Dr. Blanford; and it is quite incorrect to quote examples like this as lending support to the view that all oceanic islands are of volcanic origin. JOHN W. JUDD.

NOTES.

IN the list of Birthday honours the merits of many different classes of public servants are duly recognized. The services of men of science in the Science and Art Department, however, following an unbroken rule, fail to receive any acknowledgment.

AMONG those who have received the honour of C.B., we are glad to see the name of Prof. W. C. Roberts-Austen, F.R.S., Assayer to the Royal Mint.

THE date of the second *soirée* of the Royal Society, to which ladies are invited, is fixed for June 18.

THE Jubilee of the Uniform Penny Post was well and worthily celebrated at the Guildhall on Friday last, the 16th inst., by the Corporation of the City of London. The grand old hall was never applied to a better purpose. Every process connected with Post Office work, from telegraphy to sorting, was shown in actual operation. The Exhibition remained open for three days, and 25,000 people were delighted.

ON May 15 an influential deputation from the Marine Biological Association of the United Kingdom waited upon the Chancellor of the Exchequer to ask for an additional grant from the Treasury in aid of investigations in connection with food-fishes, crustacea, and mollusks, carried on by the Association. Mr. Joseph Chamberlain, M.P., introduced the deputation. Both he and Sir E. Birkbeck, M.P., called Mr. Goschen's attention to the large amount spent by the United States in the encouragement of the fishing industry; and Sir E. Birkbeck pointed out that even Scotland, with her grants to the Scotch Fishery Board, is in this respect ahead of England. After some remarks from other members of the deputation, the Chancellor of the Exchequer, in reply, said that the questions which had been put by him in the course of the speeches were not made from a critical or carping point of view, but merely to convince himself as to what were really the aims of the Association, which he regarded as excellent; but he could not say anything as to the practicability of their being carried out. He pointed out that the Treasury would very carefully consider the whole question of how to recast the Fisheries Department, but he felt that it would be an inconvenient thing to have four bodies, two in England and one each in Scotland and Ireland, whose jurisdiction might overlap. He hoped to be able in a short time to have an opportunity of consulting some of the scientific and other gentlemen present, in order to have further light thrown upon the subject before the Government took any action in the matter.

AT the Royal Institution, on Tuesday afternoon, May 27, Mr. Andrew Lang will begin a course of three lectures on "The Natural History of Society." The remaining lectures will be given on June 3 and 10.

MR. G. BERTIN is about to deliver, at the British Museum, a series of four lectures on the manners and customs of the Babylonians, from the cuneiform documents in the Museum. The lectures will be given on the following Tuesdays—June 3, 10, 17, and 24, at 3.30 p.m.

ON Monday evening Mr. T. W. Russell asked in the House of Commons whether the Committee consisting of certain members of the Royal Society appointed to inquire into the question of lighthouse illuminants had yet reported. Sir M. Hicks-Beach replied that there had been some unavoidable delay in the matter in consequence of a change made in the composition of the Committee. But he had communicated with the President of the Royal Society, and understood that the Report of the Committee might be expected in the course of the summer.

MR. F. H. SNOW, of Lawrence, Kansas, calls attention in *Science* to a remarkable fall of meteorites of unknown date in Kiowa County, Kansas. "Many of the citizens of Greensburgh, the county seat, were," he says, "aware of the existence of these strange irons, and commonly called them meteoric; but there seems to have been no suspicion of their true character and value. Indeed, until March 17, 1890, a specimen weighing 101·5 pounds, had ornamented the side-walk in front of a real estate office in the above-named town for about three years. The farmers in the vicinity of the locality where the fall had occurred had put some of the specimens to various uses." Prof. W. Cragin, of Washburn College, was the first scientific man who visited the farm upon which the meteorites had fallen. This was on March 13. He secured from one of the farmers five meteorites, aggregating in weight over a thousand pounds, the

heaviest specimen weighing 466 pounds. Mr. Snow himself shortly afterwards visited the place several times, and obtained five specimens, one of them being the meteorite which had been used as an ornament of a side-walk. The total number of masses included in the fall was at least twenty; and Mr. Snow says that the total weight of all the masses must have exceeded two thousand pounds. They fell within an oval area about one mile in length. "Some of the specimens were only partially buried in the ground; others were struck by the breaking plough at a depth of from three to four inches; others at the second ploughing, five or six inches deep; others yet, by the stirring plough at the third ploughing in a subsequent season." A specimen retained for the museum of the University of Kansas weighed 54·96 pounds. "It is," says Mr. Snow, "an irregular plum-shaped mass, much pitted, and covered with a burned and weathered crust. Its extreme length is about eleven inches, and its breadth is seven inches. This specimen as well as the others mentioned above, so far as examined by the writer, belongs to that class of meteoric iron known as 'pallasite.' It is composed of nickeliferous iron, including many cavities throughout the entire interior. These cavities are filled with troilite and a yellowish, glassy mineral, which is probably olivine. Some of the latter is very dark and less transparent. The specific gravity, determined by Mr. E. C. Franklin, our assistant in chemistry, and obtained by weighing the whole mass, is 4·76. Two hundred and ninety-three grams have been removed from the larger end of the specimen, and a polished surface of about fifteen square inches has been obtained, which shows very well the structure. The Wiedmanstaeten figures, rather coarse in outline, were developed readily upon the polished iron surface by the application of nitric acid. The portion removed from the specimen is being used for analysis by Prof. E. H. S. Bailey and Mr. E. C. Franklin, and the results of the analysis will appear later."

M. V. FAYOD, of Nervi, near Genoa, has been appointed assistant in the bacteriological laboratory of the Faculty of Medicine in Paris.

THE post of Director of the Botanic Garden at Hamburg, vacant by the death of the late Prof. H. G. Reichenbach, will not at present be filled up: the Garden will remain under the care of the present Inspector, assisted by the botanists Sadebeck and Dingler.

Notarisia is no longer the only botanical journal in Italy devoted to the interests of algology. The first number has been issued of *La Nuova Notarisia*, a quarterly journal with a similar scope, published at Padua, under the editorship of Dr. G. B. De Toni, Director of the Botanic Garden at that University.

THE *Canadian Record of Science* for April records the opening of a botanical laboratory in connection with the McGill University, Montreal, under the control of Prof. D. P. Penhallow. The course of study to be pursued at the laboratory, which is furnished with microtomes, embedding baths, &c., embraces a thorough grounding in vegetable histology, and carries on those students who may desire it to a study of tissues and their constituent elements, and to the complete histology and life-history of plants.

THE Bulletin of the Torrey Botanical Club records that Miss Mary E. Banning has presented to the New York State Museum of Natural History a magnificent volume of illustrations in water-colour, accompanied by manuscript descriptions of about 175 species of the Fungi of Maryland, belonging mostly to the Hymenomycetes and Gasteromycetes.

THE trustees of Columbia College, New York, have adopted a report which, according to the *Nation*, completely reorganizes the College, and puts it definitively on the footing of a University, with faculties of philosophy, political science, mines, and law, each independent in its own sphere, but working under a University Council, made up of representatives of each faculty, and of some selections made by the President. The University will give the Master's and Doctor's degrees, and the Council will "advise the President as to all matters affecting these degrees, the correlation of courses, the extension of University work in new and in old fields, and generally as to such matters as the President may bring before it." The *Nation* attributes much importance to this change, which, it thinks, "must have the effect of stimulating the love of culture among the undergraduates, of making the University, more than ever, what all our colleges ought to be, but what only a few really are, a seat of learning."

GREAT efforts are being made in the United States to secure that American industrial products shall be well represented at the forthcoming Jamaica International Exhibition. A Committee has been appointed to make all necessary arrangements; and one of the advantages already obtained for exhibitors is that low freight rates will be charged for exhibits.

THE Smithsonian Institution has issued the tenth of the Toner Lectures, which have been established at Washington by Dr Joseph M. Toner, of that city, for the promotion of medical science. The new lecture is by Dr. Harrison Allen, and is entitled "A Clinical Study of the Skull." It is described by the author as "a contribution to the morphological study of diseased action." He expresses a hope that the results he has expounded may excite increasing interest in the proposition that "medicine for the most part is a science based on biology." "The study of biology," he says, "should not be the preparatory work of the tiro only, but should be the subject of increasing assiduity in every phase of medical work. The study of anatomical variation in the human frame is a phase of biology, and it is held in this connection to be a subject as important as any other which may claim the attention of the student of etiology of disease."

THE United States Hydrographic Office has called attention to the fact that the Bordeaux Chamber of Commerce has offered a series of prizes in order to induce masters and officers of vessels to test thoroughly the use of oil at sea. There are three sets of prizes, each set consisting of a first prize of 200 francs and a second prize of 100 francs. These prizes will be awarded for the best reports received by January 31, 1891, based upon actual experience.

ON Monday evening last, at the Surveyors' Institution, London, Mr. R. F. Grantham, M.Inst.C.E., read a paper entitled "The Encroachment of the Sea on some parts of the English Coast, and the best means of arresting it." After bringing forward evidence to show the rate of erosion on various parts of the coast, the author referred to several works for defending the coast-line from encroachment, best adapted for various situations, and described a system of groyning which had been successful for the past twelve years at Shoreham, Sussex, in protecting some land lying below the level of high-water of the tides, and in driving high-water mark further seawards. He suggested that in some instances where shingle travelled along the coast, inasmuch as groynes were necessary to protect sea-walls, the sea-walls might be omitted, and thus a substantial saving in the first cost of protection might be effected.

THE Pilot Chart of the North Atlantic Ocean shows the tracks of nine cyclones during the month of April; only five of these were of noteworthy severity: one, moving between Scotland and Iceland on the 1st and 2nd was the same great storm that gave birth to the tornado which wrecked Louisville on March 27. Another noteworthy cyclone originated north of Bermuda on the 1st, moved north-easterly at the high velocity of about 1080 miles a day, causing terrific gales along the transatlantic routes, and disappeared near Iceland on the 4th. A new feature during the month was the very unusual easterly

movement of the ice, so that, in addition to the large number of bergs south of the Banks, ice was constantly reported almost as far east as the 35th meridian, in latitude 46° and 47° N.

DR. MAX BUCHNER, who has spent a year and 9 months in Australia, Japan, China, and Manilla, has returned to Munich. He has brought back a valuable scientific collection for the Ethnographical Museum, of which he is the director.

Engineer and *Engineering* for May 16 print excellent leading articles on the disastrous accident to the West Coast Scotch express at Carlisle, on March 4; their principal reason being that the Board of Trade Report has just been issued, and that it is in many respects a remarkable document. The accident, as our readers will remember, was due to the driver losing control of the train on entering Carlisle Station, where it ran into a Caledonian engine waiting at the other end of the station. The Report issued by the Board of Trade contains all the available evidence, and the Inspector's opinions as to the cause. The question to be settled was, Why or how did the driver lose control of the train? The Inspector held that the driver was in fault, and this in the face of much evidence that did not support his theory. This evidence he got rid of by the simple expedient of rejecting it as untrue. Our contemporaries clearly demonstrate the real cause of the brake failure, and point out that the Board of Trade Inspector, even after the inquiry, did not understand the construction and working of the North-Western automatic vacuum brake, and that, therefore, his opinion is not worth the paper it is written on. For instance, in his Report he is evidently under the impression that it is possible for the driver to alter the working of the train-brake from automatic to non-automatic working from the foot-plate—an impossibility. The accident was caused by the train-pipe between the engine and train becoming blocked by ice, and thus causing the train-brake to become gradually useless, owing to the connection with the engine being closed. The engine-driver had no means of knowing this state of affairs except by applying the brake, which he did on approaching Carlisle, and found it of no use. The Board of Trade Inspector has thrown the blame of the accident on the driver—a man who, according to the evidence, displayed exceptional presence of mind in what he did. Had the Board of Trade Inspector been a trained railway engineer, he would certainly have come out of this inquiry more satisfactorily. The inquiry, or rather the result of it, distinctly points to the anomaly of officers, however eminent, adjudicating on matters concerning which they have not been thoroughly instructed.

IN the year 1886, when Mr. John Gardiner was scientific adviser to the Board of Agriculture of the Bahamas, he was asked by Governor H. A. Blake to prepare a list of the flora of the colony. At the same time a list of the plants of New Providence, prepared some years before by Mr. L. J. K. Brace, was placed at his disposal. With this as a base, Mr. Gardiner set to work, and in due time his task was accomplished. The list, with notes and additions by Prof. Charles S. Dolley, has now been printed in the Proceedings of the Academy of Natural Sciences of Philadelphia. It is called provisional, as Mr. Gardiner explains in an introductory note, mainly because it is not backed throughout by herbarium specimens.

MR. GEORGE W. PERRY, of Rutland, Vt., writes to *Science* that European furze grows in one spot in the island of Nantucket, where it has maintained itself for fifty years. It was introduced by an Irishman, "who was homesick because it did not grow about his cabin, as in the old country." Mr. Perry believes it has not spread to any great extent. "It may be interesting to some," he adds, "that the Scotch heath also is found in one spot in the island, where it has continued for a long time." Mr. George M. Dawson, of the Geological Survey of Canada, also writes to our American contemporary about gorse or furze in the New World. He says it has for many years been fully naturalized in the southern part of Vancouver Island, where, along road-sides and in waste places near Victoria, it is very common. The broom is also abundant in similar situations in the same locality, and "both plants appear to be as much at home as in their native soil."

THE new number of the Journal of the Anthropological Institute of Great Britain and Ireland contains, among other papers, an interesting address by the President, Dr. John Beddoe, in the course of which he refers to the vexed question as to the original seat of the Aryan race. Speaking of the fact that the Lithuanian language is regarded by some philologists as "the most primitive in form of the whole Aryan family," he points out that we have little definite knowledge as to the physical type of the Lithuanians. "Here, then," he says, "is a fine opportunity, well within reach, for a partisan of the European-origin theory. Let him go to Kovno or Vilna, and bring us back, thoroughly established, the true Lithuanian type."

A DETAILED description of the useful minerals and mineral waters of the Caucasus, by Prof. V. Möller, has appeared at Tiflis. The author is at the head of the Mining Administration of the Caucasus, and has availed himself of all accessible information on the subject. The work is illustrated by a map. It appears as the third volume of the second series of "Materials for the Geology of the Caucasus."

THE U.S. Department of Agriculture has issued Parts I., II., and III., of a valuable "Bibliography of American Economic Entomology." These parts relate to the more important writings of B. D. Walsh and C. V. Riley, and have been prepared by Samuel Henshaw.

MESSRS. CROSBY LOCKWOOD AND SON will publish immediately a new "Pocket Book" for electrical engineers, which has been written by Mr. H. R. Kempe, of the Postal Telegraphs Department. They have also nearly ready a new work on "Electric Light Fitting," a practical hand-book for working electrical engineers, by Mr. John W. Urquhart, whose book on "Electric Light" is well known.

THE same publishers have in the press a new elementary treatise on "Light," for the use of architectural students, by Mr. E. W. Tarn, forming a new volume of "Weale's Rudimentary Series"; also a revised and enlarged edition of Prof. Merivale's "Notes and Formulæ for Mining Students"; and a new edition of Mr. G. W. Usill's "Practical Surveying."

WE understand that Mr. Caleb Pamely, of Pontypridd, has in the press a comprehensive treatise for the use of mining engineers, dealing with the whole subject of colliery working and management. It will be published by Messrs. Crosby Lockwood and Son.

AT a recent meeting at Shanghai of the China Branch of the Royal Asiatic Society, Dr. Macgowan, the veteran scholar, presented a paper on the political domination of women ("gynæcocracy" or "gynarchy") in Eastern Asia. In the opening of the paper reference was made to the condition of the aboriginal peoples whom the Chinese found on the Yellow River on their arrival from Akkad. The Chinese then possessed the rudiments of civilization, of which the aboriginals were destitute. That this irruption of the Chinese was anterior to the invention of cuneiform writing in Akkad was probable, because of their use of quipos or knotted cords in keeping records. These quipos, the author said, and not mere tradition, were the base of Chinese archaic annals, and from them the earliest form of Chinese written characters was evolved. Anterior to these quipos, judging from certain neighbouring tribes, notched sticks were employed. With regard to the tribes which the Chinese

found existing on reaching their future home, Dr. Macgowan remarked that the philosopher of Universal Love, Motzu, proto-altruist and arch-heresiarch—whose sun was rising when the sun of Confucius was setting—enunciated views on the evolution of the state and family which are in accord with those of modern anthropologists. Men at first were in the lowest state of savagery: there was no Golden Age as depicted by sages and political philosophers until men felt the necessity of a remedy for the anarchy that prevailed. Practices of self-deformation were some of them remarkably curious, such as those of drinking through the nostrils, extracting front teeth and substituting dogs' teeth, head-flattening, &c.; the most striking was the attempt to raise a polydactylous race, by destroying all children who came into the world with the usual number of fingers and toes, and thus a tribe had a dozen fingers and as many toes. The writer then described a number of instances of rule by Amazons, and observed that it is chiefly among the aboriginal inhabitants that the chieftaincy of women obtains to this day. There is seldom an age in which one tribe or another does not afford examples; the more primitive the condition of these tribes the slighter is sexual differentiation as regards public governmental affairs, both civil and military. It was owing to rumours respecting tribes of this kind that fables and myths in Greece arose regarding Indo-Scythian Amazons. The paper, which is full of valuable ethnological matter, will be published in the Journal of the Society.

A PAPER upon the spontaneously inflammable liquid hydride of phosphorus, P_2H_4, is communicated by Drs. Gattermann and Haussknecht, of Heidelberg, to the new number of the *Berichte* (p. 1174). Owing to the disagreeable and highly dangerous properties of this substance, its chemical history has never been completed; very little, indeed, has been hitherto added to our knowledge concerning it since its discovery by Thénard in 1845. The Heidelberg chemists have devised a much better mode of preparing the liquid from phosphide of calcium, by means of which it is obtained in a state of almost perfect purity. A Woulfe's bottle with three necks and of about two litres capacity is three parts filled with water. The central tubulus serves to introduce a wide tube of 15 mm. diameter expanded into a funnel at the top and passing down to about three centimetres beneath the water. One of the side necks is fitted with a cork and a bent tube just dipping beneath the surface of the water, through which a current of hydrogen gas can be driven. The third tubulus carries the delivery tube which permits of the escape of first the hydrogen, and afterwards the products of the reaction between the calcium phosphide and the water, into a special form of condensing arrangement. The Woulfe's bottle is placed in a capacious water-bath, which is heated to 60° C. as soon as all the air is expelled by the current of hydrogen. The calcium phosphide is then introduced through the central wide tube in pieces about two grams in weight, until, in about 15–20 minutes' time upwards of 50 grams have been added. The escaping gases pass first through an empty wide test-tube in which most of the admixed water-vapour is condensed, then into an upright tube, narrowed in its lower half, and closed at the bottom, which forms a suitable receptacle for the liquid hydride. By means of an exit-tube the remaining gases are permitted to escape; owing to a little admixed and uncondensed vapour of the liquid, they burn spontaneously at the mouth of the tube. The condenser is surrounded with iced water instead of a freezing mixture, so that the condensation may be observed. In about five minutes after commencing the operation clear colourless highly refractive drops of the liquid form and run down into the narrower portion of the condenser, about 2 c.c. being obtained from 50 grams calcium phosphide. The experiment must not be performed in sunlight, otherwise the liquid rapidly decomposes, in the manner described by Thénard, into gaseous PH_3 and solid P_4H_2. By a slight addition to the above arrangement, all three hydrides of phosphorus may be simultaneously prepared. The escaping gases are allowed to pass through a large flask containing hydrochloric acid, which decomposes the vapour of the remaining liquid hydride, and large quantities of the yellow solid P_4H_2 separate out. The escaping gas, which may be collected over water, is non-spontaneously inflammable, and consists of practically pure PH_3. Liquid P_2H_4 boils constantly and without decomposition when not suddenly heated at 58° under a pressure of 753 mm. Its specific gravity at 12° is 1·007, nearly the same as that of water. Exposed to sunlight it becomes yellow in half an hour, due to the formation of solid P_4H_2, which remains at first dissolved; after 2–3 hours' exposure, the yellow solid begins to separate out, and in 1½ days 0·2 gram is totally decomposed, in accordance with the equation $5P_2H_4 = 6PH_3 + P_4H_2$. Consequently, sealed tubes containing this substance exposed in daylight are very dangerous articles. Owing to the accumulation of PH_3 gas, they are apt to explode with deafening concussion and production of a wide-spreading and very brilliant flame, especially if the drawn-out end becomes accidentally broken off.

THE additions to the Zoological Society's Gardens during the past week include a Wanderoo Monkey (*Macacus silenus* ♀) from the Malabar Coast of India, presented by Miss Eileen Martin; two Leopards (*Felis pardus*) from India, presented by Mr. — Egerton; two Yellow-winged Blue Creepers (*Cœreba cyanea*) from South America, presented by Mr. H. E. Blandford; two Mandarin Ducks (*Æx galericulata* ♂ ♀) from China, presented by Mr. C. J. Kingzett; two —— Touracous (*Corythaix* sp. inc.) from South Africa, presented by Mr. C. W. Burnett; two Undulated Grass Parrakeets (*Melopsittacus undulatus*) from Australia, presented by Mr. A. Golden; two Common Vipers (*Vipera berus*), British, presented respectively by Mr. W. H. B. Pain and Mrs. Mowett; an Australia Peewit (*Lobivanellus lobatus*) from Australia, presented by Capt. Shepherd; a Himalayan Bear (*Ursus tibetanus* ♂), two Bengal Foxes (*Canis bengalensis*), two —— Hares (*Lepus macrotis*) from India, a Ruffed Lemur (*Lemur varius*) from Madagascar, deposited; two Bar-tailed Pheasants (*Phasianus reevesi* ♀ ♀), an Amherst Pheasant (*Thaumalea amherstiæ* ♂) from China, a Variegated Sheldrake (*Tadorna variegata* ♀) from New Zealand, two Black-headed Conures (*Conurus nanday*) from Paraguay, purchased; a Crested Porcupine (*Hystrix cristata*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

OBJECTS FOR THE SPECTROSCOPE.

Sidereal Time at Greenwich at 10 p.m. on May 22 = 14h. 1m. 54s.

Name.	Mag.	Colour.	R.A. 1890.	Decl. 1890.
			h. m. s.	° ′
(1) G.C. 3770	—	White.	13 59 17	+52 54
(2) 69 Virginis	5·5	Yellowish-white.	13 21 35	−15 24
(3) B.A.C. 4699	5	Yellowish-red.	14 3 32	+44 23
(4) 20 Boötis	5	Yellow.	14 14 36	+16 49
(5) η Boötis	3	Yellowish-white.	13 49 30	+18 57
(6) U Cygni	Var.	Very red.	20 16 11	+47 33

Remarks.

(1) This very large nebula (101 M Boötis) has not yet been spectroscopically examined. According to the Parsonstown observations, it is at least 14′ across, and exhibits a spiral structure with arms and knots. It is everywhere faint, except in the middle. In the General Catalogue it is described as: "Pretty bright; irregularly round; at first gradually, then very suddenly much brighter in the middle to a small bright nucleus." The

spectrum of such a diffused mass is likely to possess great interest, and the nebula is so large that it will probably not be difficult to differentiate the spectra of different regions.

(2) In his catalogue of stellar spectra, published in 1887, Konkoly records an observation of this star, in which bright lines were strongly suspected. Notwithstanding the recent additions to this group by Prof. Pickering and Mr. Espin, the number is still very small, and it is important that suspected cases should be fully investigated. The lines suspected by Konkoly in 69 Virginis were C, D_3, and F—the three commonly observed in β Lyræ and γ Cassiopeiæ. It is quite possible that the appearance of the lines is periodic, and observations should therefore be continued for some time. If the lines are of any considerable brightness, the observations ought not to be difficult, as the bright lines in the 8th magnitude stars in Cygnus are easily seen and measured with 10 inches aperture. Any irregularities in the continuous spectrum, especially in the green and blue, should be noted; and, if possible, comparisons should be made with the carbon flutings. Prof. Lockyer has pointed out that a line near λ 447 is associated with D_3 in the Orion nebula, and also in the solar chromosphere, and it is important to observe whether this also applies to the bright-line stars. He has demonstrated by photographs that the line in the nebula (447) is coincident with one of the bright lines photographed by Prof. Pickering in P Cygni.

(3) Dunér describes the spectrum of this star as a magnificent one of Group II., particularly in the red end. The bands 1–9 are all strongly marked. The star is thus probably a little more advanced in condensation than the mean species of the group, and it will be interesting to know what line-absorptions appear at this stage, and also what is the extent of carbon radiation.

(4 and 5) These are given in Vogel's catalogue as stars of the solar type and of Group IV. respectively. The usual observations are required in each case.

(6) This is one of the very few variables with spectra of Group VI. So far, we have no records of any changes in spectra which may accompany the variations in magnitude, and the cause of the variability is, consequently, very imperfectly understood. Dunér says that the spectrum consists of three zones rather feebly developed, band 6 (near λ 564) being weak, but he does not state the magnitude of the star at the time of his observation. The next maximum will occur about May 28. The star ranges from about magnitude 7·5 to < 11 in a period of 461 days. Changes of colour should also be noted.

A. Fowler.

Spica.—At the Berlin Academy of Sciences on April 24, Prof. Vogel announced that Spica consists of two close stars revolving round their common centre of gravity. The star's spectrum is that of Class IV., and twice in April 1889 the F line appeared to be shifted towards the violet end of the spectrum as compared with the H β line given by a vacuum tube, whilst once in the following month the shift appeared to be towards the red end. These observations and others made this year of the star's motion in line of sight are given in the following table, approach to the sun being indicated by (−) and recession from the sun by (+), both being expressed in German miles per second:—

Potsdam Mean Time.		h. m.	Observed Motion	Relative to the Sun.	✶−☉
1889 April	21	9 15	−11·6	−0·7	−12·3
,,	29	11 10	−12	−1·2	−13·2
May	1	10 58	+7·5	−1·3	+6·2
1890 April	4	11 30	−3·4	−0·5	−2·9
,,	9	10 30	−14·2	+0·2	−14·0
,,	10	11 30	−0·3	+0·1	−0·2
,,	11	10 50	+7·6	0·0	+7·6
,,	13	10 50	−14·7	−0·1	−14·8
,,	15	10 0	+11·3	−0·3	+11·0

The observations have been reduced to the epoch 1890, April 2, 10h. Potsdam mean time, and the period of revolution of the system determined as 4 days 0·3 hours. The greatest motion in line of sight due to the orbital velocity is about 12 miles a second, and the system as a whole is moving towards the earth with a velocity of about 3 miles a second.

From this it is found that the distance between the components of the system is 660,000 miles, and their total mass = 1·2 that of the sun.

It will be remembered that Algol is a spectroscopic double of the same character as the above described.

The Meteoric Theory of Comets.—In the *Sidereal Messenger* for May, Mr. W. H. S. Monck discusses the evidence that has been brought forward in support of this theory, and in connection with the meteoritic origin of the universe. Only four comets are definitely known to be connected with meteor-showers; and conversely, only four meteor-showers have been connected with comets; these comets are all periodic, the longest period being 415 years. From this fact it is argued that there is not sufficient evidence to allow the assertion that all comets are connected with meteor-swarms and that the ejection theory advocated by the late Mr. Proctor is supported. It is asserted that, since an ejection from a rapidly cooling body may be partly solid, partly liquid, and partly gaseous, the gaseous matter might form the comet and the solid (or solidified) matter form the attendant meteors; but for this origin to be true the assumption must be made that two planets exist beyond Neptune. Mr. Monck argues that because Arcturus was seen through 90,000 miles of Donati's comet, whereas Saturn's rings (except perhaps the inner crape ring) are not transparent, the rings must be more than 1000 times as dense as the comet at the point where it crossed between us and Arcturus, hence meteoritic collisions should be more frequent and the effect of the increased temperature should be made clearly manifest in the spectrum. The meteoritic hypothesis is not, however, objected to as a working hypothesis, but is said to be on an equality with the older nebular hypothesis; and the writer does not think the spectroscope will ever afford a crucial test between the two, for the reason that it cannot distinguish between a large solid, surrounded by a gaseous envelope, and a number of small bodies with interspaces filled with gas.

Mass of Shooting-Stars.—Mr. C. C. Hutchins, in the *American Journal of Science* for May, gives the result of an investigation undertaken with the object of finding data for determining the mass of shooting-stars. Having determined the radiant energy of the standard candle, it was found that on the supposition that the rays of a meteor have the same ratio of visible to total energy as those of the candle, the mass of a meteor at a distance of 50 miles, having a magnitude equal to Vega and a velocity of 25 miles per second, would be 0·2936 gram if it continued two seconds. If the meteor in burning produce, for a given expenditure of energy more light than the candle, then a less mass would serve to produce the light given by it. A lump of the Emmett Co. (Iowa) iron meteorite was placed upon the lower carbon of an arc lamp and vaporized by the passage of the current, and it was found that for a given expenditure of energy the arc of meteoritic vapour gave ten times the light of the candle, hence the mass of a meteor giving the light of a first magnitude star moving with parabolic velocity, and lasting for two seconds, is 0·029 gram.

Photographs of the Moon.—Admiral Mouchez, at the meeting of the Paris Academy of Sciences of May 12, presented a note on some new photographs of the moon obtained by the Brothers Henry at Paris Observatory. The instrument used was the equatorial 0·32 metres aperture, destined for the map of the heavens. The photographs are said to be far superior to those obtained in England and the United States with larger apertures, the superiority of the results being ascribed not only to the perfection of MM. Henry's objectives, but also to the method of direct enlargement adopted.

THE ROYAL SOCIETY CONVERSAZIONE.

The *conversazione* held by the Royal Society on May 14 was in every way most successful. The attendance was large, and everyone was pleased and interested by the programme. We note some of the objects exhibited:—

The Director-General of the Geological Survey exhibited:—(1) A series of specimens illustrating deep borings in the south of England. In this case was arranged a series of cores and specimens from all the deep bores which during the last thirty years have been made in the south of England in search of water. They included the borings at Richmond, Crossness, Kentish Town, Meux's Brewery, Streatham, Turnford, Ware, Chatham, Gayton and Orton in Northamptonshire, Harwich, and Swindon. The positions of these bores were shown on the large index

map suspended in the same room.—(2) Series of specimens illustrating the dynamical metamorphism of rocks. This case contained an important collection of specimens from Switzerland, Norway, and Scotland, illustrating some of the more remarkable effects of the mechanical deformation and recrystallization of rocks. The first series was one of specimens of Triassic and Jurassic dolomites and limestones from Canton Glarus, showing the extraordinary manner in which these rocks have been squeezed and puckered. Attention was particularly directed to the evidence afforded by the fossils (*Belemnites*) of the extent to which the strata have been stretched in some parts. The second series, from the south of Bergen, showed the presence of recognizable Silurian corals and trilobites in rocks which have been so much metamorphosed as to have acquired the characters of finely crystalline phyllite or micaceous schist. The third series, from the north-west of Scotland, illustrated how a massive quartzite, full of annelide-tubes, has been crushed and recrystallized until it has assumed the structure of a quartz-schist, and all trace of the fossils has been obliterated. The effects of mechanical movements even among the comparatively young and soft rocks of the south of England were illustrated by two specimens placed in this case from the under-surface of a "thrust-plane" in the vertical chalk of the Dorsetshire coast. They showed how the chalk has been indurated, smoothed, and polished by the movement of the overlying mass. A view and section of this thrust-plane were placed beside the specimens.

Specimens of minerals brought from Ceylon by C. Barrington Brown, exhibited by Prof. J. W. Judd, F.R.S. Large perfectly crystallized and clear beryl, 2650 grammes in weight. The specimen, though water-worn, exhibits the crystalline form. The colour is intermediate between that of emeralds and aquamines. The specific gravity is 2·703. Fine crystal of yellow corundum (oriental topaz). Well developed crystals of corundum (sapphires, &c.). Crystal of chrysoberyl from the same district.

Maps to illustrate magnetic surveys of special districts in the United Kingdom, exhibited by Profs. Rücker and Thorpe, FF.R.S. The arrows represent the horizontal disturbing forces in magnitude and direction. The figures give the vertical disturbing force in terms of 0·00001 C.G.S. units, taken as positive when it acts downwards. In some maps, regions of great (downward) vertical force are indicated by deeper tints. Map 1. Indications of an attracting centre at sea, to the south of the Hebrides. Map 2. Horizontal disturbing forces at stations near the boundaries of a district in Yorkshire and Lincolnshire, within which there is a locus of attraction. Map 3. Regions of high vertical force within the above district. The highest observed values are at Market Weighton and Harrogate. Map 4. Ridge line or locus of attraction drawn (continuous line) by connecting stations of maximum vertical force, and (dotted line) by connecting points midway between the stations at which the direction of the horizontal force disturbance changes. Map 5. Ridge line, 150 miles long, probably correct to within five miles for the greater part of its length.

Mr. C. V. Boys, F.R.S., exhibited:—(1) Oscillating spark experiment. This is a modification of the method employed by Dr. Lodge to show the oscillatory nature of a spark formed under proper conditions. Six lenses are mounted on a disk, and are made to rotate. Each forms upon a screen an image of the spark, which is drawn out by the movement of the lens into a broken band of light. The lenses are not exactly the same distance from the axis, so that the band formed by one is not overlapped by the band formed by the next. Thus the whole duration of the spark from the first to the last oscillation may be observed or photographed.—(2) Photographs showing the formation of drops. Water drops, half an inch or more in diameter, were allowed to slowly form and break away in a liquid of slightly lower specific gravity—namely, a mixture of paraffin and bisulphide of carbon. Photographs of these were taken as follows: they were illuminated by an electric arc and large condensing lenses, a camera was placed in front, and the view was rendered intermittent by a card disk with one hole near the edge made to rotate at from fourteen to twenty turns a second. The exposure was about one eight-hundredth of a second. Forty inches of photographic plate were arranged in a long slide which could be drawn past by hand. Three of these multiple photographs are exhibited. The thaumatrope was made by sticking the separate parts of the last series round a card disk, and afterwards painting the surface black and white, following the outlines of the photographs exactly. The thaumatrope clearly shows the gradual formation of the drop and the spherule, the oscillation of the pendant drop immediately afterwards, the rebound of the spherule from the pendant drop, the oscillation of the large drop as it falls, and its rebound from the water below into which it fell. Other photographs are shadows of water jets cast upon a photographic plate by the action of a small distant spark, a method invented by Mr. Chichester Bell. The remainder are photographic shadows cast by a water jet upon a rapidly moving plate by the intermittent light of an oscillating spark. These clearly show the movement of the separate water drops.

Sugar-cane (*Saccharum officinarum*) seed and seedlings, exhibited by Mr. D. Morris. There appears to be no authentic record of any really wild station for the sugar-cane, and the fruit has not hitherto been figured or described. At Barbados, several times during the last twenty years, and more recently by Prof. Harrison and Mr. Bovell, self-sown seedlings of the sugar-cane have been observed. The subject was taken up systematically in 1888, and about sixty of the seedlings raised to mature canes. Many of these exhibited well-marked characteristics differing from the varieties growing near them. Careful inquiry has shown that canes known as the "purple transparent" and "white transparent," and possibly also the "Bourbon" cane, produced seeds in very moderate quantities. Spikelets received at Kew have been examined and the seed found *in situ*. It is anticipated that, by cross-fertilization and a careful selection of seedlings, it will now be possible to raise new and improved varieties of sugar-cane, and renew the constitutional vigour of plants that have become deteriorated through continuous cultivation by cuttings or slips. Great importance is attached to the subject in sugar-producing countries, as it opens up an entirely new field of investigation in regard to sugar-cane cultivation.

Prof. H. Marshall Ward, F.R.S., exhibited a selection of transparent photographs, showing (1) the habits, &c., of various trees from different parts of the world; (2) the comparative structure and anatomy of several European timbers; and (3) some of the more prominent features of diseases of wood, &c., and fungi causing them.

The electrification of a steam jet, exhibited by Mr. Shelford Bidwell, F.R.S. The shadow of a small jet of steam cast upon a white wall is, under ordinary conditions, of feeble intensity and of a neutral tint. But if the steam is electrified, the density of the shadow is at once greatly increased, and it assumes a peculiar orange-brown hue. The electrical discharge appears to promote coalescence of the exceedingly minute particles of water contained in the jet, thus forming drops large enough to obstruct the more refrangible rays of light. It is suggested that this experiment may help to explain the intense darkness, often tempered by a lurid yellow glow, which is characteristic of thunder-clouds. See *Phil. Mag.*, Feb. 1890, p. 158.

Mr. Killingworth Hedges exhibited:—(1) Gramme dynamo worked as a motor, fitted with bearings of a new carbon composition, which does not require oil for lubrication.—(2) Vortex speed indicator, driven by the above, fitted with oilless bearings.

Lord Rayleigh, Sec.R.S., exhibited:—(1) An instrument for testing colour vision.—(2) Polarization of light by chlorate of potash crystals.

Photographs of eggs of the Great Auk, exhibited by Mr. Edward Bidwell. There are 67 recorded eggs of this extinct bird, of which 45 are in Great Britain. The collection of photographs exhibited consists of two views each of 53 of these eggs, photographed to scale.

Specimens of Simony's Lizard (*Lacerta simonyi*), from the lonely rock of Zalmo, near the Island of Ferro, Canaries, exhibited by the Zoological Society of London. A rare lizard, only known from this spot, and said to feed on crabs. These lizards were obtained by Canon Tristram, F.R.S., during his recent visit to the Canaries, and presented to the Zoological Society by Lord Lilford.

Electric-radiation meter, for obtaining quantitative measurements of the intensity of the radiations emitted by an electric oscillator, exhibited by Mr. Walter G. Gregory. Its action is based on measuring the increase of length of a stretched wire, or strip of metal, when heated by the currents induced in it by the rapidly varying field of force. In the instrument exhibited, the elongation of a fine platinum wire is shown by attaching to one end of it a fine helical spring made by winding a thin metallic ribbon round a cylinder. As the wire extends the spring rotates, and the motion is further magnified by a small mirror which reflects the image of a wire on a scale. The oscillator is

of the usual type, and is worked by an induction coil and four accumulators, the latter kindly lent by the Electric Construction Corporation.

Breath figures, showing that polished surfaces placed near to bodies in low relief often take an impression of the detail, which is made visible by breathing upon the surface (the period of exposure varying in different circumstances), exhibited by Mr. W. B. Croft. (1) A coin is lightly pressed on a freshly split surface of mica for 30 seconds; the mica takes a breath figure of the detail of the coin. (2) Paper printed upon one side has lain for 10 hours between two plates of glass; the print appears in white letters on both. Part of this phenomenon, although not with print, was noticed by Moser in 1840. (3) Sometimes the print appears in black letters; the same impression may change from white to black. (4) Coins are put on the two sides of a piece of glass and electrified for two minutes; each side has a perfect impression of that side of the coin which faced it. An electrotype plate may be reproduced in a similar way. These effects were partly indicated by Karstens in 1840. (5) An electric spark is sent across glass. Five superposed bands appear, black and white, of decreasing breadths, as well as three permanent scars. Riess, 1840. (6) The microscope shows water particles over the whole surface, larger or smaller as the effect is black or white.

Prof. Silvanus P. Thompson exhibited:—(1) Optical rotator. This apparatus is for rotating the plane of polarization of light, and is intended to be used in conjunction with polarizing reflectors (black-glass mirrors, &c.), which do not admit of being bodily rotated around the axis of the beam of light. The principle of the new rotator consists in the employment of two quarter-wave plates of mica, one of which is fixed at 45° across the plane-polarized beam of light, which it thus converts into circularly-polarized light. The second quarter-wave plate, which can be rotated by a simple gear, reconverts the circularly-polarized beam into plane-polarized light, vibrating in any desired azimuth. (Constructed by Messrs. Newton and Co.)—(2) Natural diffraction-grating of quartz. This specimen of iridescent quartz exhibits diffraction-spectra corresponding to those of a grating ruled to 12,000 lines to the inch. A microphotograph taken by Mr. C. L. Curteis, with a Reichert's apochromatic (3 mm.) lens, shows the nature of the minute structures of the specimen. For the sake of comparison, a diffraction-grating of 6000 lines to the inch, photographed on glass, is exhibited beside the piece of quartz.—(3) New straight-vision prisms, consisting each of a single prism of Jena glass, of very wide angle, immersed in cinnamic ether. The materials having identical mean refractive index, rays of mean refrangibility pass straight through. (Constructed by Messrs. R. and J. Beck.)—(4) Colour experiments. Two liquids, incapable of mixing, are placed over one another in a flat bottle. They are chosen so that each absorbs all the rays that the other one can transmit. Though each is transparent, they are jointly absolutely opaque. They are also opaque when shaken up together.

Experimental illustration of the recent investigations of M. Osmond on molecular changes which take place during the cooling of iron and steel, exhibited by Prof. W. C. Roberts-Austen, F.R.S. In the case of mild steel, containing 0·5 per cent. of carbon, as it cools down from a temperature of 1100° C., two points may be observed at which heat is evolved. The first of these occurs at 750° C., and marks the change of β (or hard) iron to α (or soft) iron. The second evolution of heat is observed at 660°, and is due to a change in the relation of the carbon and iron. M. Osmond, in continuing an investigation made by Roberts-Austen, has shown that the presence in iron of elements with small atomic volumes retards the change of β to α iron, and, conversely, elements having large atomic volumes hasten the change.

Specimen of phosphorous oxide, and apparatus for preparing same, exhibited by Prof. Thorpe, F.R.S., and Mr. Tutton. This substance has been shown by the exhibitors to be represented by the formula P_4O_6. It crystallizes in monoclinic prisms melting at 25°·5, and boils in an atmosphere of nitrogen or carbon dioxide at 173°. Cold water dissolves it with extreme slowness, forming phosphorous acid. With hot water, strong caustic alkalies, chlorine, bromine, and alcohol it reacts with great energy, generally with inflammation. Oxygen slowly converts it, at ordinary temperatures, into phosphoric oxide, and under diminished pressure the combination is attended with a faint luminous glow similar to that observed in case of phosphorus. No ozone, however, is formed. At slightly higher temperatures the oxidation is brought about instantly with production of flame. Phosphorous oxide possesses the smell usually attributed to phosphorus, and which is identical with that noticed in match manufactories. It is highly probable, as Schönbein surmised, that the element phosphorus is without smell, and that the smell ordinarily perceived is due to a mixture of ozone and phosphorous oxide. Phosphorous oxide is highly poisonous, and it is not improbable that phosphorus necrosis is caused by this substance.

Photographs of the spectrum of the nebula in Orion, exhibited by Prof. J. Norman Lockyer, F.R.S. These photographs were taken in February with the 30-inch reflector at Westgate-on-Sea, the exposures varying from 2 to 3 hours. The one taken with a 3 hours' exposure (February 10) shows about 50 lines between λ 500 and λ 373, but many of them are only visible with difficulty, especially in artificial light. The Henry Draper Memorial photograph of the spectrum of P Cygni was shown for comparison, and it was seen that all the bright lines were amongst the brightest in the nebula. This argues in favour of the view that stars with bright-line spectra are of a nebulous character.

Photograph of the two clusters (33 and 34 ♅ VI.) in the sword-handle of Perseus, showing remarkable coronal and festoon-like groupings amongst the stars on several parts of the photograph, exhibited by Mr. Isaac Roberts. These clusters are quite free from nebulosity, and in this respect they differ from other clusters which Mr. Roberts has photographed; for those clusters are involved in faint but distinct nebulosity.

The larvæ of Amphioxus, exhibited by Prof. E. Ray Lankester, F.R.S.

A selection from the butterflies collected in the great equatorial forest of Africa by Mr. William Bonny, one of Mr. Stanley's staff, exhibited by Mr. Henley Grose-Smith. Little was known of the Lepidoptera of this part of Africa; few of the species collected by Mr. Bonny have been previously recorded from that region, and nine are new to science. The collection includes, amongst others, the great *Papilio antimachus*, also *Papilio zalmoxis*, and many West African species.

Collection of iridescent crystals of chlorate of potash to illustrate the production of colour and its intensification by reflection from multiple thin plates, exhibited by Dr. Alex. Hodgkinson.

Dr. Alexander Muirhead exhibited:—(1) Some patterns of Dr. Lodge's lightning protector for cables and for telegraphic work generally. In these instruments a series of air-gaps, separated by self-induction coils, are offered to the lightning, or other high-tension currents, which have got into the line. The greater part of the flash jumps the first air-gap, most of the residue jump the next, and so on, until after four or five dilutions nothing is left which can break down the thinnest insulation, or appreciably affect even a delicate galvanometer connected to the protected terminals.—(2) Muirhead's portable form of the Clark standard cell, in cases, with thermometer.—(3) Standard condenser, ⅓ microfarad (with Dr. Muirhead's certificate).—(4) Set of Thomson and Varley slides, small.—(5) Saunders's capacity key, suitable for Dr. Muirhead's capacity test.—(6) Saunders's reversing key.

Specimens of aluminium and alloys manufactured by the Aluminium Company, Limited, exhibited by Sir Henry E. Roscoe, F.R.S. Pigs of aluminium, 99 per cent. pure. Castings in aluminium, rough and finished. Specimens of aluminium, soldered. Aluminium wire, sheet and drawn rod. Aluminium medals, plain and gilt. Cast aluminium bronze and brass, showing (*a*) tensile strength and elastic limit; (*b*) twisting stress; (*c*) thrusting stress, long specimens; (*d*) thrusting stress, short specimens. Stampings in aluminium bronze, rough. Ten per cent. aluminium bronze, twisted cold. Five per cent. aluminium bronze, worked hot and cold. Aluminium brass, worked hot and cold. Aluminium bronze and brass sheet.

Specimens illustrating ancient copper and bronze from Egypt and Assyria, exhibited by Dr. Gladstone, F.R.S. The collection consists of borings from tools found by Mr. Flinders Petrie, at Kahun, in Egypt, and which belong to the XII. Dynasty—about B.C. 2500; also from other tools found at Gorub, which belong to the XVIII. Dynasty—about B.C. 1450. There are also fragments of Egyptian bronze figures from Bubastis, and of Assyrian bronze from the gates of the Palace of Shalmanezer II., at Balawat—about B.C. 840; as well as two pieces of slag from the old copper mines of the Sinaitic Peninsula, which were worked by the Egyptians in very early times, and discontinued after the XVIII. Dynasty. The principal point illustrated is the fact that the earliest metal implements were of copper, containing a very little arsenic and tin, probably as accidental im-

purities, and that afterwards tin was added to the copper in increasing proportions with the object of producing a hard alloy.

Mr. Percy Newberry, exhibited by permission of Mr. W. M. Flinders Petrie :—(1) Three pages of an ancient Egyptian book on medicine written on papyrus, by a scribe named Usertesen Sen, in the twenty-sixth or twenty-fifth century before Christ. This papyrus, together with a number of others of the same date referring to miscellaneous subjects (letters, legal documents, accounts, a fragmentary treatise on mathematics, &c.), was recently discovered by Mr. W. M. Flinders Petrie, during excavations in a ruined town of the XII. Dynasty, at Kahun, in Central Egypt. It contains directions for the use of midwives, written in black and red ink, in hieratic characters (a cursive or written form of hieroglyphics). The black ink is used in the body of the work for the symptoms, diagnoses, and prescriptions, and the red ink is used at the heads of the sections. The following translation of the last two and a half lines of the first page will serve to show the kind of directions given in this ancient work :—" *Treatment of a woman*[1] who is pained in her legs and in all her limbs, as one who is beaten. *Say with regard to her*,[1] it is the growth of the *at* (vulva). *Do thou with regard to her*[1] thus : let her eat grease until she is cured."—(2) Facsimile of an unpublished papyrus preserved in the British Museum containing medical prescriptions written in the Egyptian hieratic writing of the XIX. Dynasty (B.C. 1400–1200). This papyrus is chiefly interesting from the fact that it contains prescriptions copied from an earlier work, now lost, which is said (by the ancient copyist) to have dated from the IV. Dynasty (*circa* B.C. 4000). Facsimiles of these two papyri, together with translations, notes, &c., will shortly be published, under the editorship of Mr. F. Ll. Griffith and Mr. Newberry.

Egyptian spear-head of bronze, bearing the name and titles of Kames, a king at the end of the XVII. Dynasty, *circa* 1750 B.C., exhibited by Dr. John Evans, Treas. R.S. The blade is cast, and the socket is made of hammered bronze, and these two pieces that form the weapon seem to have been "burnt" together.

MM. Richard Frères, Paris, exhibited :—(1) Continuously recording hair hygrometer. This is the latest form of the Saussure hair hygrometer, so much used on the Continent, owing to its working satisfactorily when most other hygrometers fail, viz. near 32° F. In some of Saussure's instruments more than one hair was used, but in none did the apparatus give a continuous record. In the present hygrometer, the expansion and contraction of a bundle of hairs raise and lower a pen, which leaves on a paper-covered cylinder a continuous record of the humidity of any position, garden, or sick-room in which it may be placed. —(2) Curves produced by the anemometers on the summit of the Eiffel Tower, and on that of the Central Meteorological Office at Paris. These show (1) that the average velocity of the wind on the top of the tower (994 feet) is about 3½ times that at 66 feet, and (2) that the hour of greatest average velocity on the summit was 11 p.m., whereas at 66 feet (as at most observatories), it was 1 p.m. ; so that the times of maximum and minimum are almost precisely reversed.—(3) Isochronous regulator for electric contacts. An instrument for making and breaking electrical contact at equal intervals of time.

Chætopodæ, Medusæ, Ascidians, Nudibranchs, and other Invertebratæ, prepared as lantern slides, showing not only the general form, but also much of their anatomy, exhibited by Mr. H. C. Sorby, F.R.S. The success of the method depends on the fact that when soft-bodied animals are dried on glass the extreme edge dries first, and adheres firmly, so that on further drying the animal does not contract irregularly, but becomes thin and flat, and shows like a drawing projected on the plane of the glass. In many cases the natural colour is well seen, but in other cases artificial staining is used, which brings out the anatomical structure to great advantage. In some cases the specimens are best seen by reflected light, and it is then well to use a photographic slide, taken under such conditions. Some details may also be brought out to greater advantage by means of a properly developed photograph.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Among the distinguished persons on whom honorary degrees will be conferred at the *Comitia Maxima*, on June 10, are the following :—Mr. Henry M. Stanley, Sir Andrew Clark, F.R.S., President of the Royal College of Physicians, Jonathan Hutchinson, F.R.S., President of the Royal College of Surgeons, George Richmond, R.A. (retired), Prof. J. J. Sylvester, F.R.S., Dr. John Evans, Treasurer R.S., and Alexander J. Ellis, F.R.S.

A discussion by the Senate took place on May 17, on the proposal, recently referred to in NATURE, that the experimental work in chemistry carried on by candidates previous to the Natural Sciences Tripos Examination (Part II.) should be allowed to count in determining the places in the Class List. The opinions expressed by members of the Senate were, in general, unfavourable to the proposal, as tending to diminish the confidence felt in the independence of the Examiners. It was stated that it would be impossible to make commensurable in practice the testimonials to the work of candidates given by different teachers ; and further, that it would tend to make the superintendence of that work more formal, and so diminish its freshness and originality.

The Council of the Senate report that in January 1887, the late Mrs. Clerk Maxwell bequeathed the residue of her estate to the University for the purpose of founding a Scholarship in the Cavendish Laboratory at Cambridge, to be called the "Clerk Maxwell Scholarship." The estate of the testatrix has now been realized, and the residuary account furnished by the executors shows a balance of £5963 14*s*. 10*d*. with accruing interest on the sum of £5000 deposited with the National Bank of Scotland. After consulting the Lucasian and Cavendish Professors and Mrs. Clerk Maxwell's executors, the Council have framed regulations for the Scholarship, of which the following are the most important :—

A Scholarship to be called the Clerk Maxwell Scholarship shall be instituted in the University in connection with the Cavendish Laboratory, for the advancement by original research of experimental physics, and especially of electricity, magnetism, and heat.

The person elected to the Scholarship shall be called the Clerk Maxwell Student in Experimental Physics.

Any member of the University who has been a student for one term or more in the Cavendish Laboratory shall be eligible for the Scholarship.

The Electors to the Scholarship shall be the Cavendish Professor of Experimental Physics and the Lucasian Professor of Mathematics, and in case of any difference of opinion between them the final decision shall rest with the Master of Trinity College or with someone specially appointed by him for this purpose.

The Electors, in electing the student, shall be guided by the promise shown by the candidate of capacity for original research in experimental physics, and shall take such steps as they may think desirable to enable them to form a judgment of such promise.

The student so elected shall devote himself, under the direction of the Cavendish Professor, to original research in experimental physics within the University ; he may, however, carry on his researches elsewhere if he has first obtained the written permission of the Cavendish Professor to do so.

The Scholarship shall be tenable for three years, and a student who has once held the Scholarship shall not be capable of re-election.

SCIENTIFIC SERIALS.

THE most important paper of original research in the numbers of the *Journal of Botany* for March, April, and May, is the conclusion of Mr. G. Massee's "Monograph of the Genus *Podaxis*," in which he gives his views of the systematic position of this genus of Fungi consequent on some recent discoveries as to its structure, together with descriptions of the seven known species, one of them new.—Messrs. H. and J. Groves describe and figure an interesting addition to the British flora in the minute *Nitella Nordstedtiana*.—Dr. W. O. Focke gives a description of no less than fifty-two species or forms of British *Rubi*.—Mr. R. A. Rolfe contributes a monograph of a small and interesting genus of Orchids, *Scaphosepalum*.—Mr. E. M. Holmes enumerates the marine Algæ of Devon.—Messrs. Britten and Boulger's "Biographical Index of British and Irish Botanists," has now advanced as far as the letter Q.

[1] In red ink.

WITH the exception of an enumeration of the flora of the little island of Giannutri, off the coast of Tuscany, the number of the *Nuovo Giornale Botanico Italiano* for April is chiefly occupied with a report of the meetings of the Italian Botanical Society, held sometimes at Florence, sometimes at Rome. The papers here reported are mostly of interest to Italian botanists: those of more general importance being chiefly by Prof. Arcangeli, who continues his researches on the interesting points of structure in the anatomy of *Euryale*, and other members of the water-lily family.

Memoirs of the St. Petersburg Society of Naturalists, Zoology and Physiology, vol. xix. No. 2.—The article on the fauna of the White Sea, by V. M. Shimkevitch, contains two separate monographs. One of them deals with the *Balanoglossus*, and is a detailed anatomical research into its structure, thus making a most valuable addition to the work of Kovalevsky, Agassiz, Metchnikoff, Spengel, Balfour, and Bateson. The author's conclusions are, that the *Balanoglossus* occupies an intermediate position between the worms and the *Chordata*. It has originated from a trochozoon which acquired some features in common with worms, as well as some features distinctive of the *Chordata*. The other monograph deals with the *Enteropsis dubius*, a new parasitic species closely akin to Aurivillius's *Enteropsis sphinx* (*Krustaceer hos arktiska Tunicater*). The morphology and embryology of this new Copepod are dealt with, and they are followed by general remarks about the history of development of parasitic *Copepods*. Both papers are well illustrated with plates.—A paper by N. N. Polejaeff deals rather too shortly with the following topics: on the filaments which are found in the *Hircinidæ* sponges; on spermatogenesis of the *Porifera*; on the anatomy of *Chalinidæ*; on the *Luffaria*; and on the new genus of *Porifera*, the *Korotnewia desiderata* (with plates).—The appendix to the same volume contains a detailed experimental inquiry, by A. Gendre, into the causes of death in animals when the excretory functions of the skin are artificially stopped.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 8.—"On the Heating Effects of Electric Currents. No. IV." By William Henry Preece, F.R.S.

The following table gives the fusing constants and fusing temperatures for all the metals in general use when bare and exposed in still air:—

	Fusing constant. (a)	Fusing temperature. ° C.
Copper	2530	1054
Silver[1]	1900	954
Aluminium	1873	650
German Silver	1292	1200
Platinum	1277	1775
Platinoid	1173	1300
Iron	774·4	1600
Tin	405·5	226
Lead	340·6	335
Alloy (lead 2 parts, tin 1 part)	325·5	180

The table means that if we take, for example, a uniform copper wire of 1 cm. diameter, a current of 2530 amperes will raise it to 1054° C., and therefore fuse it; and if we take any conductor of copper of similar form, but of different diameter (d), the fusing current (C) is

$$C = 2530d^{\frac{3}{2}}.$$

The fusing current of any other material is obtained from the equation

$$C = ad^{\frac{3}{2}}.$$

It seemed natural that these constants, marking such a distinct and well-defined fiducial point, should also enable us to obtain the currents that would raise the wire to any other temperature.

It is shown that if we determine C for any temperature, then, since $\theta = \kappa C^2$, θ being the rise of temperature, the current C′ producing any other temperature θ' is obtained by means of the equation

$$C' = C\sqrt{\frac{\theta'}{\theta}}.$$

[1] G. Roux, *L'Électricien*, December 14, 1889.

Now, for copper of 1 cm. diameter C = 2530 for 1054°. Thus, if we want to find the current that will raise such a conductor to 13°, we have

$$C' = 2530\sqrt{\frac{13}{1054}} = 281 \text{ amperes,}$$

if the surface be equivalent to the normal surface at white heat.

The coefficient which converts this normal surface emissivity to that of the surface of ordinary wires at low temperatures by taking the normal surface as unity, is as follows:—

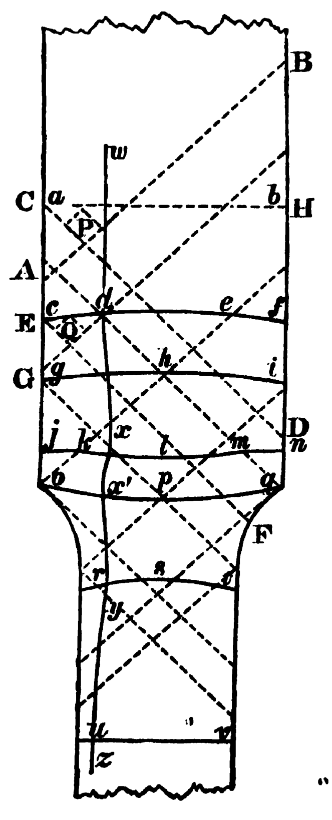
	Surface coefficient.
Bright and polished copper	0·5
Copper, dirty, oxidized, or blacked with shellac varnish	0·6
Copper, well coated with lamp-black	1·0

Thus, the current (C) producing 1054° (θ) in a bare bright copper cylinder of 1 cm. diameter is 0·5 × 2530 amperes, and that which would produce a temperature of 10° C. is

$$0{\cdot}5 \times 2530\sqrt{\frac{10}{1054}} = 123{\cdot}2 \text{ amperes.}$$

Thus, if we know the current producing any fixed temperature in any cylindrical conductor, we can readily calculate the current required for any other temperature.

Physical Society, May 2.—Prof. W. E. Ayrton, President, in the chair.—Mr. C. A. Carus-Wilson read a paper on the distribution of flow in a strained elastic solid. The author pointed out that when a bar is subjected to tensile stress the elements of the bar are distorted by the resulting shearing stresses which attain maxima in planes at 45° to the axis. If the bar be supposed to be divided into elements such as P or Q (see Fig.), then if the shearing strains are equal in the two directions



parallel to the sides of the elements, the bottom points of the strained elements will be directly below their top corners, whereas if the strains be different in the two directions there will be a displacement to one side or the other depending on which side the greater strain occurs. Since each inclined section is subject to the same total shearing force, the shearing strain along any section such as EF may be taken as inversely proportional to the length of the line EF, the bar being supposed of uniform thickness. From these considerations it may be seen that an element P will be subject to equal strains, for AB = CD, hence the lower point of P will remain vertically below its upper point. In this region, therefore, a horizontal straight line drawn

on the unstrained bar will remain horizontal and straight on the strained bar. An element at Q, however, will be subjected to unequal strains, for EF is $<$ GH, hence the lower points of the elements will be displaced towards the axis. This displacement will increase as the distance beyond *d* and *e* from the axis increases, and an originally horizontal line will become curved at the ends *cd* and *ef*, whilst *de* will remain straight. In a similar way it was shown that horizontal lines should assume the shapes indicated at *ghi*, *jklmn*, *opq*, *rst*, and *uv*, in their respective positions, whilst vertical lines should become pinched inwards above and below the shoulder as shown by the curve *wxx'yz*. To test whether the reasoning, by which the above conclusions were arrived at, was satisfactory, a copper bar was carefully prepared, ruled, and subjected to permanent strain. The curvatures of the various lines clearly show the characteristics predicted by theory. Prof. Perry inquired whether it was correct to assume the stress uniform over the plane sections inclined at 45° to the axis. He also said that the general character of the flow somewhat resembled that of a viscous fluid passing from a wide to a narrower channel. Prof. Herschel thought Mr. Carus-Wilson justified in assuming the stress uniform over the diagonal sections; the latter said he only made the assumption as a provisional hypothesis, but the results of his experiment agreed so closely with his theoretical deductions that he thought the hypothesis correct.—Mr. C. V. Boys made two communications, (1) on photographs of rapidly moving objects, and (2) on the oscillating electric spark. A collection of apparatus by which he had been able to photograph drops of water in their various stages of formation was exhibited. It consisted of a lantern and lenses by which a trough in which the drops were formed could be strongly illuminated, combined with a camera and revolving disk with one perforation. By this means exposures of about 1/600 of a second could be made about 20 times a second. The slide of the camera was about 3 feet long, and could be moved across the field by hand so as to take the consecutive impressions on different parts of the plate. The resulting photographs show with remarkable clearness the formation, breaking away, the oscillations of the drops, and their rebounding in the liquid into which they fall. By cutting the photographs into strips, each strip representing a single exposure, and mounting them on a disk, Mr. Boys had arranged a kind of thaumatrope which represented the phenomena in a very realistic manner. He also exhibited photographs of small water fountains broken up into drops by musical sounds, which he had taken by the electric spark without the aid of lenses. The shadows of the drops were sharply defined even when magnified considerably, and the various stages of transition from the liquid column to the detached particles were well shown. Finding it possible to obtain such good results from a simple spark, it occurred to him that he might get a succession of photographs from the intermittent light of an oscillating spark, and in this he was fairly successful. An apparatus devised to show the oscillatory character of a discharge was next exhibited in operation. It consisted of a disk carrying six lenses arranged in two sets of three. The members of each set were at different distances from the axis so that the images of the spark on the screen do not coincide. The disk can be revolved at a high speed, and the successive sparks are seen as bright patches on the screen. By this apparatus a single discharge can be examined, whereas with Dr. Lodge's apparatus it is desirable to have a fairly rapid succession of sparks. Photographs of an oscillatory discharge taken with the apparatus were exhibited, and these show that the duration of the illumination is a considerable fraction of a complete period. Lord Rayleigh said he was greatly interested by Mr. Boys's apparatus. He (Lord Rayleigh) had photographed water fountains both when broken up, and when made to coalesce under electrical influence, but it had never occurred to him that it would be possible to get enough light or sufficient sharpness from a single spark. Mr. Boys's success he believed to be owing to the fact of his using no lenses, which would absorb the ultra-violet rays. He also thought the method might be developed so as to give shaded pictures instead of mere representations in black and white. Mr. Gregory asked Mr. Boys if he had tried to get greater potentials for his oscillatory discharges by using Dr. Lodge's "impulsive rush" arrangement. Mr. Trotter inquired whether the single sparks used to photograph the water fountains were as large as those required to show oscillations. Mr. Boys said he had not tried Dr. Lodge's "impulsive rush" arrangement because of the enormous capacity of the condensers required. The sparks used to photograph the broken up fountain were very small, being only about ¼ inch long, and from a few jars. Prof. Perry asked Lord Rayleigh whether it would be possible to compare the shapes of the water drops shown in the photographs with the shapes of the liquid surfaces of revolution given by Sir William Thomson at the Royal Institution some years ago, or whether the changes of shape were too rapid to permit of the surface tension being all important. Mr. Boys thought the motions of the drops would be too rapid, and that inertia would play an important part. Lord Rayleigh pointed out that by forming a drop slow enough the effect of inertia might be made negligible until such time as the unstable state was reached; after that, however, inertia must have considerable influence on the shape.

Geological Society, April 30.—Dr. A. Geikie, F.R.S., President, in the chair.—The following communications were read:—On certain physical peculiarities exhibited by the so-called "raised beaches" of Hope's Nose and the Thatcher Rock, Devon, by D. Pidgeon.—The Devonian rocks of South Devon, by W. A. E. Ussher, of H.M. Geological Survey. This paper is the result of work done in continuation of the labours of the late Mr. Champernowne, and refers particularly to the area north of the Dart and east of Dartmoor. Owing to the complicated stratigraphy of the region, we have to fall back upon such information as can be procured of the general types of Upper, Middle, and Lower Devonian faunas; for though the lithological constituents of these three divisions are broadly distinguishable, there are no definite lithological boundaries between them. The Lower Devonian is mainly distinguished by the occurrence of sandstone and grit, but the upper beds are shales passing into the Middle Devonian slates. The Middle Devonian consists of limestones, and shaly limestones upon slates, the latter representing the Calceolen-Schiefer, and containing *Spinifer speciosus*. *Stringocephalus* is found here and there in the middle Devonian Limestones. The upper part of the middle Devonian Limestones (with Lummaton fauna) passes into the *Cuboides* beds of the Upper Devonian. The Upper Devonian contains thin-bedded limestones, often concretionary, with chocolate-red and pale greenish slates and mudstones. These beds correspond to the Goniatiten-Schichten, Kramenzelstein and Knollenkalk of Germany, and to the Cypridinen-Schiefer. In the Upper and Middle Devonian rocks we find a local prevalence of schalstein and tuffs, breaking up the limestones. The slate and sandstone type of Upper Devonian in North Devon appears to give place southward to a purely slate type, possibly accompanied by overlap of the Culm measures. The author groups the South Devon rocks under the following heads:—

Upper.	1. Cypridinen-Schiefer. 2. Goniatite-limestones and slates. 3. Massive Limestones.
Middle.	4. Ashprington Volcanic Series. 4. Middle Devonian Limestones. 5. Eifelian slates and shaly limestone.
Lower.	6. Slates and sandstones, generally red. 7. Slates with hard grits.

After discussing the relationship of the Lincombe and Warberry beds and the New Cut Homalonotus beds, the author notes the discovery of *Pleurodictyum* by Mr. Whidborne in the railway cutting at Saltern Cove. He proves the Lower Devonian age of the Cockington beds and their correlation with the Torquay Lower Devonian by the discovery of fossils. He considers it probable, though not certain, that the main mass of Meadfoot beds is below the Lincombe, Warberry, and Cockington sandstones. The distribution of the Middle Devonian Limestones is described. *Stringocephalus* is found in limestones containing *Rhynchonella cuboides*. The upper parts of the limestone-masses (East Ogwell, Kingskerswell, Barton, Ilsham, &c.) may be Upper Devonian. The massive limestones may terminate abruptly or pass laterally into shales, and the whole mass of the limestones seems to be replaced by slates between the Yealmpton and Totnes areas. The commencement of the phase of volcanic activity which caused the accumulation of the Ashprington series is shown to coincide with the latest stage of Eifelian deposition, and the Ashprington series may represent continuous or intermittent vulcanicity up to a late stage in the Upper Devonian. North of Stoke Gabriel a mass of limestone seems to have been formed contemporaneously with the volcanic material on the immediate borders of which it occurs. Elsewhere the limestones are interrupted by local influxes of volcanic

material. The occurrence of other local developments of Middle and Upper Devonian volcanic rocks is described. The relationship of the Middle and Upper Devonian deposits varies. In some cases Upper Devonian shales may have been deposited against Middle Devonian limestones; in others there is a continuous development of limestone, the Middle Devonian limestones being succeeded by *Cuboides* beds, *Goniatite* limestones, and Knollenkalk. The local variations of these are described, and fossil lists are given. The Knollenkalk is shown to pass under *Entomis* bearing beds ("Cypridinen-Schiefer"), which are described, though a detailed account of their relationship to the Culm-measures is reserved for a future occasion. After the reading of this paper, some remarks were offered by the President, Prof. T. Rupert Jones, Prof. Hughes, and the author.

PARIS.

Academy of Sciences, May 12.—M. Hermite in the chair.—New lunar photographs by the Brothers Henry, of Paris Observatory, by M. Mouchez (see Our Astronomical Column).—On volume iii. of the "Annales de l'Observatoire de Nice," by M. Faye.—Experiments on the deformations undergone by the solid envelope of a fluid spheroid submitted to the effects of contraction; possible applications to dislocations of the terrestrial globe, by M. Daubrée. In order to obtain the necessary oblateness, spherical balloons of vulcanized caoutchouc, having disks of the same material affixed at the extremities of a diameter, were used. The disks gradually increased in diameter, so that the thickness gradually decreased from the poles in each hemisphere, and unequal pressure was exercised on the liquid contained in the balloon. The oblateness has been determined of various liquid spheroids, and the conditions of production of ridges and fissures similar to those exhibited in the earth's crust.—On the retardation of foliation in Provence during the spring of 1890, by M. G. de Saporta. The low temperature and the abnormal humidity having exercised a very sensible influence during the spring of this year on vegetation in the middle of France, the author has investigated the state of foliation at the beginning of May in a locality situated at Saint-Zacharie (Var), in the high valley of Huveaune, at an altitude of about 200 metres.—On an hydraulic instrument with a new model of turbine for the continued utilization of the power of rivers, by M. Paul Decœur.—The difference between the surface of the earth taken as fluid and that of an ellipsoid of revolution having the same axis, by M. O. Callandreau. It is shown that in the case of a supposed fluid earth the maximum depression for latitude 45° is 9·1 metres, which agrees with the value given by M. Helmert in his "Géodésie supérieure."—On surfaces possessing a train of geodetic conjugates, by M. C. Guichard.—On some particular cases of visibility of interference fringes, by MM. J. Macé de Lépinay and Ch. Fabry.—On undulatory transverse magnetization, by M. C. Decharme. It appears from some experiments given that a continuous electric current traversing the length of a tempered cylinder of steel may become undulatory on account of the resistance which the molecular actions of the magnetic medium oppose to it.—A note by M. A. Witz describes a method of exploration of magnetic fields by tubes of rarefied gases.—On the double chlorides of iridium and phosphorus, by M. G. Geisenheimer. By heating in a sealed tube at 300° C. 1 gram of iridium hydrate with 10 grams of PCl_3 and 15 grams of PCl_5, and reheating the yellow crystalline mass obtained with $POCl_3$ to 250°, a body possessing the empirical formula $Ir_2P_3Cl_{15}$ is formed in fine clear yellow crystals. By appropriate treatment several other double chlorides are obtained therefrom. An acid corresponding to the body $Ir_2P_3Cl_{15}$ is the product obtained on evaporating an aqueous solution of the latter as far as possible. The analyses of the salts of this acid indicate that the formula for the double chloride above should be written $2Ir_2Cl_3$, $3PCl_3$, $3PCl_5$.—A note on a characteristic reaction of hydrogen dioxide, by M. G. Denigès. A 10 per cent. solution of ammonium molybdate in water added to its own volume of concentrated sulphuric acid gives with a few drops of hydrogen dioxide an intense yellow coloration.—On the existence of microlithic peridote in the andesites and labradorites of the ridge of the Puys, by M. A. Michel Lévy.—On the contact phenomena of elæolithic syenite at Pouzac (Hautes-Pyrénées), and on the transformation into *dipyre* of the felspar of the ophitic rock in the same bed, by M. A. Lacroix.—On the metamorphic rocks of Pouzac, by M. Ch. L. Frossard. These rocks, occupying a space of 1250 m. by 300 m., extending from the railway near Monloo, appear to have been principally modified by the syenite. The ophite of Palassou has hardly acted upon the surrounding rocks. The rocks of which the modifications are attributed by the author to the action of the syenite are in the state of a fragmentary breccia and are without trace of fossils or indications of stratification. They may be classed as—siliceous, hard compact argillaceous, amphibole, talcose, chloritic, limestone, and dolomite rocks.—On the organisms of nitrification, by M. S. Winogradsky. The author has succeeded in isolating the nitrifying microbe, and has found that neither its rate of multiplication nor its vigour of action is diminished by cultivation in a mineral solution quite devoid of organic carbon. The colourless microbe of nitrification is thus capable of a complete synthesis of its substance from carbonic acid and ammonia. This fact is in direct contradiction with the fundamental doctrine of physiology that a complete synthesis of organic matter only occurs in chlorophyll-bearing plants, under the action of luminous rays.

THE LABORATORY OF THE ROYAL COLLEGE OF PHYSICIANS, EDINBURGH.

Reports from the Laboratory of the Royal College of Physicians, Edinburgh. Vol. II. (Edinburgh and London: Young J. Pentland, 1890.)

THE liberal spirit in which the laboratory of the Royal College of Physicians of Edinburgh is thrown open to workers in every department of biology that bears, however remotely, upon medicine is worthy of the highest praise. That the opportunity for research thus afforded has been appreciated is well shown by this record of the work done in the laboratory during the second year of its existence. Sixteen papers are included in the volume, many of them anatomical and gynæcological, some pathological, one morphological (on the stomach of the Narwhal), and others (while including the results of studies in the laboratory) in the main clinical. This very diversity renders criticism difficult. Taking a high critical standpoint and employing as a standard the volumes which emanate from laboratories devoted to one subject—the Reports of the Physiological Laboratory of University College, London, or the studies from the Biological Laboratories of Cambridge or of Owens College, for example—it would be easy to find fault, to indicate papers that ought scarcely to be included, and to discover the absence of any series of allied researches of high scientific value, such as might be expected to be turned out in some special field of work, were the laboratory already long established, and were it given up to one branch of science, rather than intended from the first to be of use for investigations in all branches of biology. Yet to judge the volume from such a standpoint would be unfair both to the promoters of the laboratory and to those working within it. Taking medicine alone—that is to say, as apart from surgery and gynæcology—its extent is so considerable, and the topics dealt with so varied, that all original investigations, even if of equally high practical value, cannot be of equal scientific import: when surgery and gynæcology are also included, it is yet more obvious that much of the work that is rightly performed in the laboratory, while capable of almost immediate application to clinical practice, will be of a nature that does not necessarily call for great powers of original research. Clinical importance equally with scientific value must determine the inclusion of articles in such a volume as this. Herein, indeed, lies the only valid criticism that can be directed against these reports: if they be published purely as evidence of the activity of the laboratory, they well fulfil their purpose; but it is a little difficult to see what other use they possess. From the very diversity of the investigations, the reports cannot be expected to rank as useful additions to the library of the specialist in any of the subjects treated; there is too much extraneous matter. The gynæcologist will reap little benefit from the latter half of the volume, the pathologist will fail to appreciate the niceties of frozen sections of the lower portion of the body, cut in different planes. If such reports are to be of value to other workers, rather than, as I have said, as evidence of activity, they must be issued in separate parts, and, what is of still greater importance, they must assuredly not be issued at regular intervals. Successful as the laboratory has been up to the present, it is impossible to manufacture always a definite quantity of original work per annum and to order, and if it is intended to publish so many hundred pages at the expiration of every year, then it is only to be expected that many of those pages will either be work not of the highest quality, or will be upon subjects incompletely matured.

Having said thus much, it is a pleasure to draw attention to the many excellent articles that appear in these reports. The investigation by Mr. Irvine and Mr. Woodhead (the late Director) upon the secretion of carbonate of lime, a continuation of that described in the last volume, is of great importance to morphologists as well as to pathologists. In their last paper these observers pointed out that birds can assimilate and secrete carbonate from other salts of lime, as, for instance, the sulphate, and they advanced the statement that coral animals have in all probability the same power. In this communication is described the process of shell formation in the crab. The crab can produce its shell if, in the artificial sea-water with which it is supplied, the chloride be the sole calcium salt present; and the carbonate which forms the basis of the shell is deposited, it would appear, by a process of dialysis within the chitinous upper part of the epithelial cells. In this process it is suggested that phosphoric acid acts as the carrier of the lime to parts where carbonic acid is being given off; that carbonate of lime is formed in such regions; and that the phosphoric acid re-enters the circulation. It is thus rendered easy to comprehend why it is that wherever dead or vitally inactive tissue exists in the body, in bone matrix, chitin, and foci of caseous or fatty degeneration, there lime is deposited.

It has been known since 1875 that glycosuria may be only apparent, and that the agent reducing oxide of copper in the presence of an alkali, after the administration of chloral hydrate, for example, is not a sugar. Schmiedeberg and Meyer, in 1879, showed that this substance is glycuronic acid. Dr. Ashdown contributes an excellent paper upon the differentiation of this substance from glucose. From his experiments he leans to the view that there is a distinct chemical process presided over by the renal epithelium, which has as its result the formation of glycuronic acid—morphia, chloroform, curare, or one of a number of other drugs, being present in the blood.

Mr. H. A. Thomson, in his paper upon "Tuberculosis of the Bones and Joints," gives what is perhaps the most complete *résumé* of the varieties of tubercular affection in these regions that has yet appeared in our language; following König, he emphasizes the bone-factor in joint tubercle, as opposed to the synovial membrane. Dr. Cartwright Wood's paper, upon "Enzyme Action in the Lower Organisms," deals in a most suggestive manner with certain points in the biology of the Bacteria. The action of the soluble ferments produced during the growth of micro-organisms, not only in directing and controlling the growth in various media, but, as each month at the present time is yielding further indications, in producing the symptoms of disease, is a subject which before all

others deserves the attention of the medical profession, and Dr. Wood's paper is of the greatest interest in this connection.

Of the gynæcological articles, undoubtedly the most important is that by Drs. Barbour and Webster, upon the "Anatomy of Advanced Pregnancy and of Labour." The opportunities afforded to these observers have fallen to no others either abroad or in this country, and they have employed them to the full. The illustrations to their paper, as indeed throughout the Reports, are excellent.

J. G. ADAMI.

ABSTRACT MECHANICS.

Leçons Synthétiques de Mécanique générale, servant d'Introduction au Cours de Mécanique Physique de la Faculté des Sciences de Paris. Par M. J. Boussinesq, Membre de l'Institut. Publiées par les soins de MM. Legay et Vigneron, Élèves de la Faculté. (Paris: Gauthier-Villars, 1889.)

THE following *Table des Matières* will serve to show the scope of this treatise:—

1e Leçon. But de la Mécanique physique. Notions cinématiques indispensables.

2e Leçon. Les deux principes fondamentaux de la Mécanique.

3e Leçon. Forme des équations du mouvement; ce qu'on entend en Mécanique par force, forces motrices, actions mutuelles, &c. Pesanteur.

4e Leçon. Énergie potentielle interne. Action moléculaire.

5e Leçon. Principes de la conservation des quantités de mouvement et de leurs moments, pour un système matériel indépendant ou sans relations extérieures.

6e Leçon. Principes des quantités de mouvement et des moments pour un système partiel; de leur application à la formation des équations de mouvement des corps.

7e Leçon. Idées générales sur les pressions.

8e Leçon. Raisons physiologiques et psychologiques des dénominations de forces, actions, tensions, &c., employées en Mécanique. Forces d'inertie et centrifuges.

9e Leçon. Principe des forces vives pour un système partiel. Travail des forces. Énergie interne.

10e Leçon. Suite de l'étude des forces vives et du travail; flux de chaleur; loi fondamentale de la Thermodynamique.

11e Leçon. Application du principe des forces vives aux mouvements visibles ou moyens locaux; rôles qu'y prennent le travail de déformation des pressions exercées sur les particules matérielles et l'énergie potentielle de pesanteur; &c.

Such is the interesting syllabus of the subjects lectured upon by the author; and it is melancholy to think what we have lost in the treatment and illustration of such a programme at the hands of Maxwell, as a sequel and amplification of his inimitable little "Matter and Motion."

But when we open these pages we find a great contrast before us, and a great disappointment. Hardly anything more is to be found here than the elementary *banalités* of pure mathematics, in the shape of the explanation of co-ordinates and their differential coefficients as employed in representing the motion of a particle, and thence of a rigid body considered as an aggregation of particles. There is no interesting illustration or application or even diagram; merely a sequence of simple formulas of pure mathematics, interspersed with some metaphysical speculation; it is the purest of mathematics even by the side of Lagrange's "Mécanique Analytique"; we are given plenty of Mathematics, but very little Mechanics. The words of the preface to the "Lectures in Natural Philosophy in the University of Oxford," A.D. 1700, by John Keill, Savilian Professor of Astronomy, appear to be applicable even at the present day: "Although now-adays the mechanical Philosophy is in great Repute, and in this Age has met with many who cultivate it, yet in most of the Writings of the Philosophers, there is scarce anything mechanical to be found besides the Name. Instead whereof, the Philosophers substitute the Figures, Ways, Pores, and Interstices of Corpuscules, which they never saw;" &c.

These "Leçons" are the first of a course of Physical Mechanics to be delivered at the Sorbonne, with the intention of solving the Universe; but so far the author does not appear in touch with the physical questions, and he derives his mechanical notions from words in preference to facts. No doubt this is an excellent discipline for some minds, but to the applied mathematician it is devoid of all flavour.

The note to p. 34 we have found the most interesting passage in the book, pointing out that g varies with the position of the sun and moon, but that the variation would be imperceptible but for the tides.

The French have the advantage of possessing the two words *poids* and *pesanteur;* much of our own dynamical confusion would be cleared up if we had a separate word equivalent to *pesanteur*, something like *gravity*, or *gravitation*, as proposed by Thomson.

The word *force vive* for mv^2 is still allowed to appear in these pages, in spite of all the recent efforts of Thomson and Tait, Maxwell and recent writers to banish it to oblivion; this is carrying reverence for Lagrange too far for modern progress.

Maxwell's "Matter and Motion" practically covers the same ground as these "Leçons," and the two books compared would offer the best idea of the difference between the teaching of abstract Mechanics in this country and in France.

A. G. G.

OUR BOOK SHELF.

A Manual of Anatomy for Senior Students. By Edmund Owen, M.B., F.R.C.S. (London: Longmans, Green, and Co., 1890.)

THIS manual has been written from a point of view different from that usually adopted in anatomical text-books. Instead of giving a detailed systematic or topographical description of the whole of the organs or parts of the body, the author has selected those regions or structures which have a special reference to medical and surgical practice, and he has described them as fully as is necessary to bring out the points which have to be considered and attended to by the practitioner. In making his selection, he has not limited himself to a description of those parts or arrangements which are characteristic of adult structure, but he has incorporated in his book an account of such developmental anomalies as are sometimes

observed in infancy and childhood, and regarding which anxious parents require the advice and assistance of the surgeon. But, although written by a surgeon, the manual is not confined to what is commonly called "surgical anatomy." The needs of the physician have been consulted, and the position and boundaries of the heart, the lungs, and the great viscera of the abdomen have been described and illustrated by appropriate diagrams. In many instances the author seeks to give an explanation of the symptoms produced by disease of the viscera by a reference to the anatomical relations and connections of the parts.

The marvellous progress which operative surgery has made of late years is illustrated by several chapters in this manual. The antiseptic system of treatment, devised by Sir Joseph Lister, has rendered possible the performance of many operations which would not have been thought of fifteen or twenty years ago. The brain, the spinal marrow, the great serous cavities of the body, and the larger joints, are now with safety made the subjects of operative interference. No treatise on applied anatomy therefore would now be considered complete unless it embraced an account of these parts in their surgical relations, and Mr. Owen has furnished his readers with the necessary information.

The mode of treatment necessitates on the part of the reader some preliminary knowledge, so that the book is not intended for the beginner, but for the senior student and the practitioner.

Advanced Physiography. By John Thornton, M.A (London: Longmans, Green, and Co., 1890).

THIS is a continuation of the same author's "Elementary Physiography," and, to quote the preface, "It carries the student into the wider realms of Nature, and treats of advanced physiography as defined by the Science and Art Department. Whether physiography be regarded as a separate science or not, it cannot be denied that, as thus set forth, it includes a fairly well-defined and well-ordered series of facts connected with the study of the universe." This is, perhaps, the first really serious attempt which has yet been made to give anything like a full account of the whole subject, and we have no doubt that teachers will find it convenient to have all the parts thus brought together. The author has very wisely quoted the best authorities, a proceeding which is far preferable to mere paraphrase. The book is thus largely a compilation, but it is only fair to say that full acknowledgment is made in nearly every case.

Most of the important astronomical instruments are described in considerable detail, and the fundamental notions of astronomy are clearly explained. The chapters on the so-called "new astronomy" are exceptionally good for a work of this class, and it is quite evident that the author has carefully followed the latest researches. Vogel's work on the orbit of Algol and Schiaparelli's new rotation period for Mercury are included, though only recently published. There is also an excellent summary of the work which has been done in celestial photography. The chapter on the sun is very detailed, and considers all the important facts and theories. No attempt is made to discuss any disputed points—a commendable feature in a school text-book.

There are apparently few mistakes, but one is of sufficient importance to be referred to. On p. 249 it is stated that the dark bands in stars like α Herculis are probably due to carbon absorption; this ought to read metallic fluting absorption, the *bright* flutings being probably due to carbon.

The book is profusely illustrated, but most of the diagrams have already seen service. The drawing of the Orion nebula is perhaps the least satisfactory. The large coloured plate is instructive, but there is a curious mistake. This has probably arisen from the fact that the plate is compiled from those which have appeared in the last two editions of a well-known text-book of astronomy, one of which was on a scale of wave-lengths, and the other on a prismatic scale. The flutings of carbon have evidently been transferred from one to the other without the necessary corrections, the result being that they are quite out of place relatively to the other spectra.

We can confidently recommend the book to all interested in the subject, whether for examination purposes or for the purpose of acquiring fairly accurate information as to the present state of our knowledge of the Earth's place in Nature.

An International Idiom: a Manual of the Oregon Trade Language, or "Chinook Jargon." By Horatio Hale, M.A., F.R.S.C. (London: Whittaker and Co., 1890.)

IN the district formerly called Oregon, which is of much wider extent than the State of Oregon, a sort of international language, known as the Chinook jargon, is current among the native tribes and white traders. It grew up about the beginning of the present century, and has been of great service not only in facilitating commerce, but in stimulating friendly intercourse between tribes who, if this strange speech had not existed, would have had no means of communicating with one another. Many of the words are of Chinook origin, but contributions have also been drawn from French and English, and various words have been formed by onomatopœia. In 1841, when connected with the United States Exploring Expedition which surveyed a part of the western coast of North America, Mr. Hale had occasion to study the Chinook jargon; and he has since taken pains to make himself acquainted with information brought to light by later investigators. In the present little volume he gives a full account of the subject, describing the origin and history of the "idiom," and presenting a grammar and dictionary, with specimens of colloquial and narrative phrases, songs, hymns, and a sermon. The facts he has brought together are of considerable scientific interest, and the book ought to be useful to travellers and settlers in the North American Pacific States and Provinces.

A Class-book of Geography, Physical, Political, and Commercial, for Intermediate and Senior Pupils. By W. B. Irvine, B.A. (London: Relfe Brothers, 1890.)

THE compilation of this volume must have cost the author a good deal of hard work, but we cannot say that the result seems to us satisfactory. The subject is treated in an extremely uninteresting way, and the appearance of the pages, with their short, jerky paragraphs and masses of disconnected facts, might alone suffice to deter many boys and girls from the study of geography. In the teaching of this subject almost everything depends on the intelligence and skill of the teacher; so that even the present work, in good hands, might be made the basis of instructive and useful lessons. But the book would increase rather than diminish the difficulties in the way of teachers who have no exceptional degree of ability or knowledge.

LETTERS TO THE EDITOR.

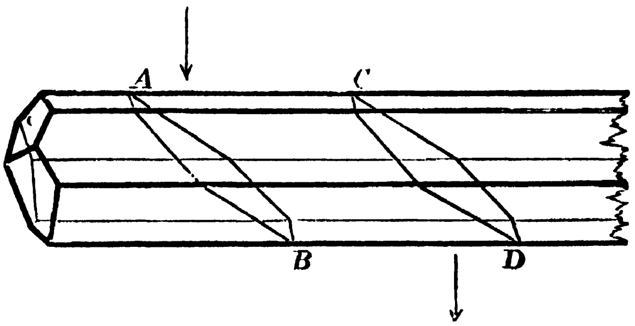
[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Idiocyclophanous Crystals of Calcite.

IT seems to have escaped notice that one at least of the many crystal-forms of calcite can be induced to show its ring-system—can be made, in fact, into a Bertrand prism—simply by proper cleavage, without any artificially-worked planes at all.

Hexagonal prisms of the mineral are of frequent occurrence; good, clear, regular-shaped specimens, 1 cm. (or more) in diameter, coming especially from Cumberland. The sides of these prisms are, of course, parallel to the optic axis; and hence a pair of opposite sides, if smooth and well developed, serve for two of the plane surfaces required for the Bertrand prism (see NATURE, May 15, p. 52) without any alteration. Moreover the crystal has a very strongly marked cleavage along the planes of the fundamental rhombohedron; and since these planes make angles of almost exactly 45° with the optic axis, a pair of them will supply the two remaining surfaces of the prism.

If, then, we select a good hexagonal prism of calcite, as shown below—



and carefully cleave it in two places, AB and CD, and allow a beam of ordinary light (preferably from an opal lamp shade) to enter the side of the prism near A, it will be affected in its passage through the crystal in the manner explained in my former letter (*ante*, p. 53), and the usual pair of ring-systems will be visible to an eye receiving the light emergent near D.

If there are any slight imperfections in the natural plane surfaces, we can easily improve upon Nature by cementing thin plates of glass upon them with Canada balsam.

Queen's College, Oxford. H. G. MADAN.

Testing for Colour-blindness.

MAY I ask, in connection with the lecture of Mr. Brudenell Carter, why those interested in the testing of colour-vision do not avail themselves of a scientific instrument like Lord Rayleigh's colour-box, wherein a given yellow has to be matched by proportions of red and green adjusted by turning a handle over a dial graduated on the back; instead of contenting themselves with crude methods, such as selection of coloured wools, which cannot give results definite enough to be of much interest, even if they were quite efficient in detecting the grossly colour-blind?

OLIVER J. LODGE.

IN Mr. Brudenell Carter's interesting paper read at the Royal Institution on Friday, May 9, a physiological explanation is suggested of an easily-verified fact of colour-perception.

An eye with the pupil dilated is proportionally more perceptive of red rays than one with the pupil contracted. If we stand at right angles to a window, or other light, shading the further eye with the hand, and look at a piece of white paper with the two eyes alternately, we shall find that, to the eye in the light, the tint of the paper seems distinctly colder than to the shaded eye.

Dr. Waelchli's observations of the retinal red zone in birds, surrounding the central green region, makes the cause of this phenomenon comparatively clear; while the phenomenon itself tends to prove that the distribution of colour-zones in the human eye resembles that of birds. E. H.

May 16.

I DO not know whether the following will be considered too trivial to be admitted as an illustration of Dr. Brudenell Carter's lecture.

About 30 years ago, being then an assistant master at a school, I one day asked an older colleague (since dead), "Who's that boy in the red cap?" Several were standing in a line, most of them with black caps. "Red cap?" said my friend; "I don't see any red cap" (it was scarlet flannel); "I can see the red head"—meaning another boy with so-called "red" hair.

The same gentleman could see no difference in colour between the flower and the leaf of the *Pirus japonica;* but it will be observed that he distinguished "red" hair without difficulty.

Otham Parsonage, Maidstone. F. M. MILLARD.

Red Spot on Jupiter.

ON May 22 last, at 15h., I observed Jupiter through a 10-inch reflector, power 252, and saw the red spot between the east limb and centre of the planet. It was rather faint, and not nearly so conspicuous as some of the belts in its vicinity. According to careful estimation, the spot reached the central meridian of Jupiter at 15h. 35m. This is 15·5 minutes before the time given in Mr. Marth's valuable "Ephemeris for Physical Observations of Jupiter," published in the *Monthly Notices* for March 1890, p. 344. The difference proves that the motion of the spot continues to accelerate in a slight degree relatively to the mean rate of rotation of 9h. 55m. 40·63s., adopted by Mr. Marth in his recent ephemerides. Observers, therefore, who wish to see the spot at mid-passage across the disk of Jupiter must turn their telescopes upon the planet at least a quarter of an hour before the predicted times based on the daily rate 870°·27.

During my observation on May 22 I saw a very dark, if not black, spot of circular form threading its way across the disk, and projected upon the northern half of the great north equatorial belt. I ascertained by reference afterwards to the *Nautical Almanac* that this object was the fourth satellite in transit.

Bristol, May 25. W. F. DENNING.

Coral Reefs, Fossil and Recent.

I PUBLISHED a review of the third edition of Darwin's "Coral Reefs," with appendix by Prof. Bonney, both in the *Biologisches Centralblatt* and in the *Naturwissenschaftlich. Rundschau* of last year. This will, I think, considerably modify the meaning of Prof. Bonney's statements, published in NATURE of the 15th inst. (p. 53), according to which I was ignorant of this work of his when I wrote my letter on "Coral Reefs, Fossil and Recent." R. VON LENDENFELD.

Swallows at Sea.

THE following notes from my journal as to meeting swallows at sea during the autumn migration may be of use to anyone interested in that subject.

On board ss. *Port Victor* from Plymouth to Sydney, 1889.—"October 31, lat. 16° N., long. 19° W. A quantity of swallows flying about the ship evidently tired and very tame, perching freely within a few feet of anyone. Look thin. A solitary swallow or two were seen yesterday and day before in lats. 20° and 24° N. respectively. 9 p.m., passed Cape Verde at a distance of forty miles.

"*November* 1.—The swallows roosted last night on board, and left during the forenoon, with the exception of one or two who remained on board all day. Saw a curlew and a wagtail at noon, lat. 12° N., long. 18° W.

'*November* 2.—One swallow still on board, roosted last night on the poop. Calm. Saw a wagtail.

"*November* 3.—Five swallows and two martins about the ship, apparently in very fair condition, so tame that they would perch on one's hand; had three or four sitting on my hand at once sometimes. Noon, lat. 5° N., long. 14° W., about 150 miles off land.

"*November* 4.—Swallows left, could not see in what direction they went. Picked up south-east trade, lat. 2° N."

HERBERT E. PUREY-CUST.

H.M.S. *Egeria*, Auckland, April 6.

The Corolla in Flower-Fertilization.

I HAVE noticed a curious fact in reference to the blue gentian of the garden here that will interest you. This flower (like the daisy) closes at night and opens in the morning, and is exquisitely sensitive to the time of sun rising and setting (it is a lasting, and with its bronzed throat an exquisite flower). The fact observed is this, that, when visited by the large handsome bee that fertilizes it, the beautiful widespread pentamerous flower closes gently on the bee, if the insect effectually enters and fertilizes it, on its passage to the honey of the five cups at the base of the corolla; and after the insect's exit, does not again unfold, if the fertilization is complete, but remains a folded flower—a protection (shorn of its beauty) for the precious seed-vessel and its maturing contents within. JOHN HARKER.

Hazel Grove, near Carnforth, May 13.

Popocatapetl.

IN vol. xli. of NATURE, (p. 592) you state: "Despatches from Mexico state that observations show that the height of the active volcano Popocatapetl has decreased by 3000 feet since the last measurement." This despatch, which was forwarded from Prof. Heilprin's party now in Mexico, would seem to indicate that there has recently been an actual *loss* of height in Popocatapetl; whereas Prof. Heilprin's object was to indicate that the observations hitherto accepted are inaccurate.

EDMUND J. DE VALOIS.

295 Adelphi Street, Brooklyn, N.Y., May 16.

CHEMICAL CHANGES IN ROCKS UNDER MECHANICAL STRESSES.[1]

AFTER pointing out that his object was to inquire how far the experimental researches of chemists and physicists are capable of affording a satisfactory explanation of the phenomena observed when the rocks of the earth's crust are studied microscopically in thin sections, the lecturer proceeded to give a *résumé* of the experimental investigations of Daubrée, Bunsen, Sorby, Thorpe, Spring, Guthrie, Fouqué, Michel-Lévy, and other chemists, who have devoted their attention to the action of pressure in influencing chemical affinity. The evidence that the deeper-seated rock-masses of the globe, and those constituting mountain-chains, have been subject to enormous pressures was then indicated; and the difference between the statical pressures arising from a great weight of superincumbent rocks, and the dynamical pressures resulting in actual movements within the earth's crust, was insisted upon. The chemical and physical principles which have been established by direct experiment, and which, at the same time, appear to be illustrated by the observations that have been made during recent years upon the minute structure of rocks, and of the minerals composing them, were stated in the following series of propositions:—

I. *In all those cases in which crystallization is accompanied by contraction, the tendency of pressure is to promote the change from an amorphous to a crystalline condition.*

Spring has shown that under a pressure of 6000 atmospheres plastic or amorphous sulphur, having a density of 1·95, passes into rhombic, crystallized sulphur, having a density of 2·05.

The mixtures of silicates which constitute the igneous rocks of the earth's crust all undergo *contraction* in passing from the amorphous (vitreous) to the crystalline condition. This is easily proved by comparing the specific gravities of more or less crystalline rock-masses with that of the glasses formed by their artificial fusion. The experiments of Delesse, Deville, Cossa, and others have shown that mixtures of the silicates of alumina and the alkalies with over 70 per cent. of silica, must undergo a contraction to the extent of $\frac{1}{11}$ of their bulk in passing from a glassy to a highly crystalline state (granite). Mixtures of the silicates of alumina, magnesia, iron, lime, and the alkalies with less than 50 per cent. of silica, in passing from a vitreous state to a perfectly crystalline one (gabbro), must undergo a reduction in bulk equal to $\frac{1}{7}$.

It may fairly be anticipated, therefore, that great pressure would tend to promote the crystallization of the mixtures of silicates composing most of the rocks of our globe, or to prevent their assuming the glassy state; and a great body of geological facts tends to support this conclusion. It must not, of course, be lost sight of that slow consolidation is also favourable to the process of crystallization, and rocks being extremely bad conductors, the process of cooling in great rock-masses is excessively slow. It is often difficult therefore to discriminate between the effects that must be referred to slowness of cooling, and those which may be safely considered to result from pressure.

As long ago as 1846, Charles Darwin showed that the andesitic lavas of the Cordillera of South America are associated with perfectly crystalline rock, true granites, made up of precisely the same minerals. The identity of the minerals in the plutonic rocks and the lavas respectively was demonstrated by the careful studies of Darwin himself, and of Prof. W. H. Miller, of Cambridge, long before the method of studying rocks in thin sections had been invented. Quite recently Prof. A. Stelzner, employing the modern methods of research, has been able to completely confirm the interesting results arrived at by Darwin and Miller, and to show that a perfect gradation can be traced between the highly crystalline "Andengranites," and the more or less glassy lavas (andesites) which are so closely associated with them.

In 1874 I was able to show that in the Western Isles of Scotland there occurred masses of perfectly crystalline (granitic) rock, identified by Zirkel as true gabbros and granites, which can be traced passing by the most insensible gradations into natural glasses ("tachylytes" and "obsidians") (Quart. Journ. Geol. Soc., xxx., 1874, 233-48), and the truth of these conclusions has been fully established by the more recent researches of Dr. A. Geikie (Trans. Roy. Soc. Edinb., 1888, 122-24, 145-50). In 1876 I further showed that the diorites and quartz-diorites of Hungary and Transylvania pass insensibly into the ordinary lavas of the district, which have the same ultimate chemical composition, and the same mineralogical constitution (Quart. Journ. Geol. Soc., xxxii., 1876, 292). In 1885, Messrs. Arnold, Hague, and J. P. Iddings, of the United States Geological Survey, established precisely similar conclusions by the study of rocks in the Nevada district (Bull. U.S. Geol. Surv., No. 17, 1885); and Signor B. Lotti, of the Italian Geological Survey, in the following year proved the same to be true in the case of the rocks of Elba.

In all these cases it is seen that the masses which have been most deeply seated, and thus subjected to the greatest statical pressures, are those which have undergone the most perfect crystallization. It must of course be remembered that in these cases the other cause tending to the development of crystalline structure comes into play—namely, slowness of cooling. The ordinary materials of igneous rocks are such bad conductors of heat, that enormous periods of time must elapse before the deeply seated portions of igneous rock-masses can become solidified.

The potent influence of this extreme slowness of cooling in bringing about the crystalline structure in molten masses of silicates has been well illustrated by the splendid researches on rock-synthesis by MM. Fouqué and A. Michel-Lévy. They have shown that the secret of making a particular mineral crystallize out of such a mass consists in finding out the temperature of fusion of the mineral, and in maintaining the molten mass for a long period just below this temperature. In the excessively slow cooling of deeply seated rock-masses, the materials must be kept successively and for long periods at temperatures a little below the fusion-points of each of their mineral constituents.

But while the influence of slow cooling in producing the crystalline structure in rocks is unquestionably very great, the effect of pressure in promoting crystallization can scarcely be doubted. We have no proof, indeed, that the holocrystalline or perfectly granitic structure of rocks can ever be produced except under these conditions of extreme pressure.

II. *Crystallised minerals, developed in a magma under pressure, may lose their stability and be dissolved by the same magma when the pressure is removed.*

The very remarkable researches of Fouqué and Michel-

[1] "The Evidence afforded by Petrographical Research of the Occurrence of Chemical Change under Great Pressure." A Lecture delivered before the Chemical Society, March 20, 1890, by Prof. J. W. Judd, F.R.S.

Lévy upon the synthesis of rocks is not less instructive, whether we consider the successes or the failures of their experiments. While able to reproduce by fusion and slow cooling—either from the powdered rocks themselves, or from duly admixed proportions of silica, alumina, iron oxide, and the alkaline earths and alkalies—various kinds of basalts and other basic rocks, all attempts to form certain other rocks, especially those containing quartz, hornblende, and muscovite, failed. The conclusion at which the experimenters arrive—and the correctness of this conclusion it is scarcely possible to doubt—is that, for the formation of such minerals and of the rocks containing them, water and other volatile substances, held within the solid mass by intense pressure, is absolutely indispensable.

Now in the porphyritic constituents (*Einsprenlinge* or phenocrysts) of many lavas, we find examples of minerals which have been formed at great depths in the earth's crust and then brought up to the surface and exposed to totally different conditions, especially as regards pressure. Very clearly do these phenocrysts tell the tale of their origin, and of the influence exerted upon them by their subsequent environments.

Crystals of quartz and felspar, which have grown to large proportions in the deeper portions of the earth's crust, are found when brought up in lavas to the earth's surface, and thus relieved from the action of pressure, to be attacked by the magma in which they were originally formed. The proof of this is seen in the corroded condition of the crystals, the glassy matter surrounding them having attacked their angles, their edges, and in a less degree their whole surface, penetrating irregularly into their interior, and reducing them sometimes to mere skeletons.

Crystals of hornblende and mica betray in an even more striking manner the effects of a change of environment. When brought up from great depths in masses of molten lava, crystals of these minerals are constantly found to be surrounded by "resorption halos." The outside of the hornblende or mica crystals, where in contact with the molten glass, is found to be attacked by it, and crystals of pyroxene and magnetite have resulted from the reaction. The action may in some cases continue till the whole of the hornblende has been converted into a pseudomorph.

In some instances there may be reason to believe that the phenocrysts have become enveloped in a magma of different chemical composition to that in which they were originally formed. But in many cases there is no room for doubt that the minerals which were formed and maintained their stability under certain conditions of pressure, lost that stability upon the diminution of pressure.

That, conversely, the increase of pressure leads to the production of a condition of instability in minerals formed at or near the earth's surface there cannot be any doubt. The study of the formation of crystalline schists from various aqueous and igneous rocks supplies us with numerous and very interesting illustrations of changes of this kind: hornblendes, chlorites, micas, and talc are produced under conditions of pressure in which pyroxenes, epidotes, felspars, and olivines lose their stability.

III. *In all those cases where solution is attended by contraction, the solvent action of water and other liquids is increased by pressure.*

That this is the case at elevated temperatures is proved by the researches of Daubrée to which we have already referred. Pure water was made to attack various silicates quite insoluble at ordinary temperatures and pressures. Even if we admit with Bunsen that there are temperatures at which this influence of pressure is no longer operative, or at which the effects are wholly inappreciable, the admission would not in any way affect the theoretical views of the geologist, seeing that the increase of temperature within the earth's crust is so rapid, that even at moderate depths the temperature at which solvent action is increased by pressure must certainly exist.

The *effects* of this solvent action under pressure are everywhere manifest when we come to the study of the rocks building up our earth's crust. At more or less considerable depths, water containing carbon dioxide has attacked the silicates composing the rock-forming minerals; so that it is impossible to find rocks which have been deep-seated, at any period of their history, in which the minerals are in a perfectly unchanged condition.

Great masses composed originally of calcic carbonate, are found to have been changed into dolomite (the magneso-calcic carbonate), or into chalybite (the ferrous carbonate); while in other cases the whole mass of a bed of calcic carbonate has been dissolved away, and silica substituted as a "pseudomorph."

We must proceed to study the details of such processes especially as they are affected by pressure and by the crystalline structure of the minerals affected.

IV. *Under great statical pressures, the whole substance of solid bodies may be permeated by fluids, and chemical reactions between them are thus greatly facilitated.*

It is not necessary to point out that the molecules of the densest solids cannot be in actual contact; this is proved by the circumstance that such solids undergo contraction by lowering of temperature, and that gases may be occluded in them. Physicists and mathematicians, as recently pointed out to this Society by Prof. Rücker, have even been able to arrive at positive conclusions concerning, not only the actual order of magnitude of molecules, but the *distances* that separate them from one another in solids.

The effect of pressure in causing the molecules of one body to pass between those of another, has been expressed by Van der Waals in the dictum, "All bodies can mix with one another, when the pressure exceeds a certain value." A similar conclusion was expressed by the late Dr. Guthrie, as the result of his experiments on potassic nitrate, when he asserted that "fused nitre and fused ice are miscible in all proportions."

Now, nothing is more certain, from petrographical researches, than that the whole substance of the minerals in the deep-seated rock-masses of the globe may be permeated by fluids. This is shown by the condition of the minerals forming these deep-seated masses.

The felspars, in their normal condition, are colourless and transparent minerals with a vitreous lustre, and this is their character when they are found in lavas and in blocks ejected from volcanoes. In granites and other deep-seated rocks, however, these same felspars exhibit grey, green, pink, or red tints, with more or less opacity, and a remarkably pearly lustre. The cause of this change of aspect is found in the fact that the unstable alkaline silicates which enter into their composition have been attacked by the fluids that have penetrated through the whole substance of the crystal, leading to the formation of the hydrated silicates of alumina, and, in some cases, the peroxidation of any traces of iron compounds that may have been present in them.

Similar changes can be shown to have affected most, if not all, the minerals which, at any period of their history have formed portions of deep-seated rock-masses.

V. *By the intimate intermixture, under great statical pressures, of solids and fluids, the properties of the former undergo great modifications.*

Bunsen, in common with all chemists who have studied the great problem of geology, has insisted that fused silicates, in spite of the high temperatures at which they assume the fluid state, obey the same laws as those governing ordinary solutions. Guthrie has shown that the principles which determine the formation of "cryo-

hydrates" and of "eutectic compounds" are equally operative in the case of the separation of minerals from a mixture of fused silicates; and the same idea has been elaborated by Lagorio. Guthrie has further shown that, as water is added to a salt, the fusion-point of the mixture is progressively lowered, and from this fact he concludes that "the phenomenon of fusion is nothing more than an extreme case of liquefaction by solution."

That silicates, when they are mixed with water, fuse at a lower temperature, was long ago recognized by geologists—long, indeed, before any physical explanation had been offered of the fact. Poulett-Scrope, Scheerer, Elie de Beaumont, Daubrée, and many others who might be mentioned, have insisted on the important part played by water in promoting the fusion of lavas and other igneous masses.

In the case of the volcanic glass known as *marekanite*, I have shown that at a comparatively low temperature the mass will, when heated, swell up and intumesce, the escaping steam causing the molten glass to froth up and assume the character of a true pumice (*Geol. Mag.*, Dec. 3, iii. 243). The brown glass ejected from Krakatão, during the great eruption of 1883, if heated, increases to many times its original bulk, and passes into a substance which, macroscopically and microscopically, is indistinguishable from the pumice thrown out in such vast quantities during that great eruption (*Geol. Mag.*, Dec. 3, v. 6).

Many volcanic glasses contain an appreciable quantity of water, amounting in some cases, indeed, to as much as 10 per cent. of their mass. The glasses which contain water fuse at a lower temperature than those which are anhydrous. There is reason to believe that most lavas are not masses in a state of simple fusion, but consist of crystals floating in a mass of mixed silicates and water, the magma being at a temperature above the fusion-point of the mixture but below that of the crystals.

VI. *Mechanical stresses, which tend to overcome the attraction between the particles of a solid, promote chemical action at those parts of its mass which are in a condition of intense strain.*

That a direct relation exists between mechanical and chemical forces is shown by the fact that capillary action is capable of overcoming weak chemical affinities. Violent mechanical shocks will sometimes completely overmaster chemical affinity, as was shown by Berthelot in the case of acetylene, cyanogen, &c., and more recently by Prof. Thorpe in the case of carbon disulphide.

Carnelley and Schlerchmann endeavoured to show that the solution of a copper wire by acid was promoted when the wire was put into a condition of strain. These experiments, it is true, yielded negative results, a circumstance which is, perhaps, hardly to be wondered at, when we remember how feeble were the mechanical forces employed.

In the case of the curiously impressed limestone pebbles of the Swiss Nagelflue, however, Sorby has shown that there are grounds for believing that solution is promoted in masses which are subjected to intense mechanical stresses, and he has confirmed this conclusion by an ingenious experiment with rock-salt (Yorksh. Proc. Geol. Soc., iv. 458–61).

Similarly impressed and faulted pebbles from the Old Red Sandstone of Stonehaven, in Scotland, have afforded what I think is indisputable evidence of the action of strain in promoting solution. The sand-grains, of which these pebbles are composed, are seen under the microscope to be traversed by bands of liquid enclosures that are clearly of *secondary* origin. Now, these bands of enclosures are parallel to the actual faults that have been produced in the pebbles, and the careful study of all the facts renders inevitable the conclusion that when the whole mass, under great statical pressures, was permeated by fluids, solvent action was determined in parts of the mass subjected to violent strain (*Mineralogical Magazine*, vii. 83).

Similar bands of secondary liquid inclusions, which have clearly been produced in the same way, abound in the crystals of many rock-masses that have been subjected to strain and movement.

VII. *Pressure may supply the conditions required for the renewal of the growth of crystals when their development has been arrested for an indefinite period, and even after they have suffered mechanical injuries.*

In 1856, Louis Pasteur published the results of his interesting investigations upon the property exhibited by bimalate of ammonia and other salts, the crystals of which are able to repair injuries produced by fracture; and this experiment has been repeated and confirmed by Scharff and other observers.

This principle of the growth and repair of injured crystals is one of great importance and wide application in geological investigation. Sorby has shown that rounded and water-worn sand-grains that have originally constituted a portion of granite or other igneous rock may, in the presence of solutions of silica and under pressure, renew their growth, and, in the end, acquire the faces and angles characteristic of quartz-crystals The observations of Becke, R. Irving, Van Hise, Bonney, and other microscopists have shown that, not only fragments of quartz, but portions of the crystals of felspar, augite, hornblende, biotite, and other minerals, may undergo enlargement in a similar way. It has further been shown that this repairing and growth of crystals is continually taking place in rocks under pressure; that the composition of the outer parts of a crystal may vary as growth goes on; and that the action can take place in solid rock-masses (Quart. Journ. Geol. Soc., xlv. 175–86).

I have found it possible to illustrate experimentally some of the phenomena exhibited by zoned crystals in rocks. An octahedral crystal of chrome-alum of a dark-purple colour was mutilated by having two opposite solid angles broken off from it and then placed in a solution of common ammonia-alum (see Fig. 1). By more rapid

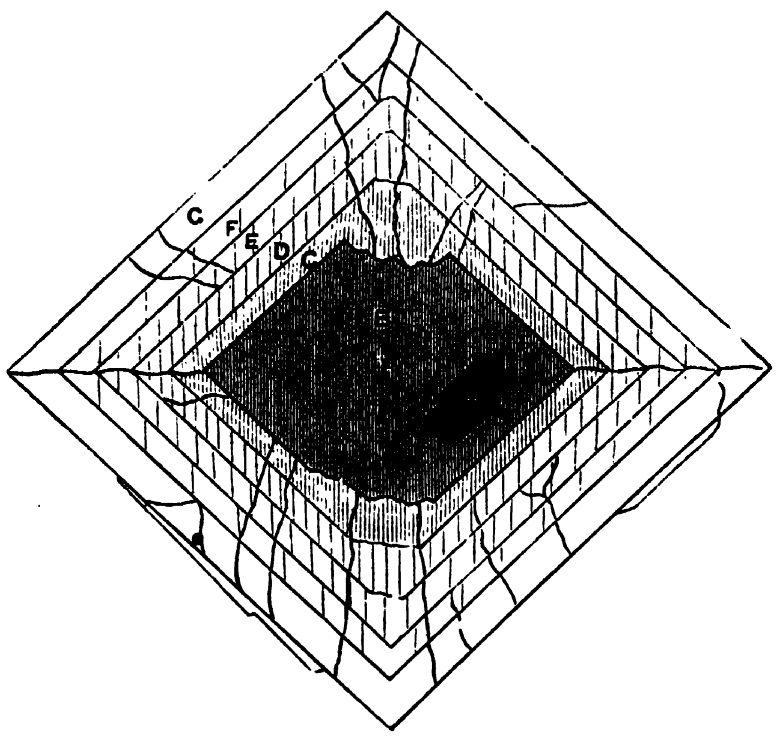


FIG. 1

growth in the injured portions, the crystal tended to repair itself, but the regularity of this process was interfered with by subjecting the crystal and solution to a somewhat wide range of temperature. As the coefficient of expansion of chrome-alum appears to be different from that of ammonia-alum, the shell of the latter material

was from time to time cracked by the unequal expansion. The solvent, finding its way into the interior, partially dissolved away the original crystal of chrome-alum. The final result of these changes was that while the form of the alum octahedron was almost completely reproduced, only a small portion (A) of the original chrome-alum crystal remained. Much of the chrome-alum was dissolved out and replaced by a mixture of the two alums (B), while the other layers of the crystal (C, D, E, F, G) were formed by still paler-coloured zones, also consisting of mixtures of a like kind. Zoned crystals exhibiting similar abnormal appearances to this alum crystal are by no means rare in some igneous rocks.

VIII. *When solution under pressure is going on in a crystalline body, the action is controlled and modified by its molecular structure. This molecular structure may have been produced either in the process of crystallization, or as the result of mechanical or other forces acting upon the crystal subsequently to its formation.*

Daniell's earliest contributions to science, in the year 1816, dealt with the remarkable and unequal action of solvents upon crystals. The curious and complicated patterns produced on the faces and the cleavage or cut surfaces of crystals (etching-figures) have subsequently been studied by Leydolt, Klocke, Baumhauer, Becke, and other investigators. The results obtained have been shown to vary with the nature and strength of the solvent, the temperature, the pressure, and the time during which the action is allowed to take place.

In 1884–85, Von Ebner, as the result of an exhaustive study of the etching-figures of calcite and aragonite, showed that crystals possess *planes of chemical weakness*, to which he gave the name of "solution-planes," these being analogous to the well-known planes of least cohesion or cleavage-planes. Quite independently, I, about the same time, arrived at the same conclusion by studying the crystals in deep-seated rocks (Quart. Journ. Geol. Soc., xli. 383, &c.). In these deep-seated rocks the crystals (their whole substance being permeated by the solvent) yield to chemical action along their solution-planes, along which hollow spaces in the form of negative crystals are produced.

When twinning-planes are developed in crystals by pressure or other mechanical agencies, these planes (gliding-planes) become planes of chemical weakness (*Mineralog. Mag.*, vii. 87). The experiments of Reusch, Baumhauer, Mügge, Foerstner, and others have shown how frequently this secondary twinning is developed in the crystals of rock-forming minerals.

When the negative crystals formed along the solution-planes of a mineral are filled with various secondary products, the whole character and aspect of the substance may be transformed. When the infilled negative crystals are of appreciable dimensions, the avanturine and "schiller" phenomena result from the action. When the action is on an ultra-microscopical scale, the phenomena of opalescence and of iridescence may be produced.

By the introduction of various substances in solution into a crystal, its composition may be altered and the way prepared for the recrystallization of the substance as a distinct mineral. It has been shown that, by the introduction of sodic chloride into a plagioclase-felspar, the way has been prepared for the conversion of that mineral into scapolite (*Mineralog. Mag.*, viii. 186).

IX. *Under great pressures, paramorphic changes take place in crystalline bodies without any alteration in their chemical composition.*

It is a well-known fact that, under the slight pressure which can be exerted by the hand, the orthorhombic, yellow variety of mercuric iodide passes into the tetragonal, red variety. Spring has shown that, under a pressure of 5000 atmospheres, monoclinic sulphur passes, at ordinary temperatures, into the orthorhombic form. Van 't Hoff and Reicher have shown that the temperature at which this latter change takes place is progressively diminished as the pressure is increased.

That slight forces acting through a considerable period of time are competent to produce such paramorphic changes has long been known. Thus the mercuric iodide and sulphur undergo their paramorphic changes slowly when subjected only to the ordinary vicissitudes of atmospheric temperature.

Many interesting examples of similar heteromorphous forms of the same compound are familiar to geologists, such as calcite and aragonite among the carbonates, and pyroxenes and amphiboles among the silicates. Heteromorphism, indeed, appears to be the rule rather than the exception in the mineral kingdom.

The slow paramorphic changes between heteromorphous forms of the same compound was long ago studied by Gustav Rose; and in more recent years the dependence of these changes on great pressures, or on small forces acting through long periods of time, has engaged the attention of J. A. Phillips, Allport, Hawes, R. D. Irving, J. Lehmann, G. H. Williams, Teall, and other observers.

In considering these paramorphic changes, it must be remembered that the transition under pressure is not always, as in the case of sulphur, from a less dense to a more dense form. On the contrary, as in the change of both aragonite to calcite and of augite to hornblende, we find the denser but less stable form passing into the less dense but more stable one. Stability, however, is only a relative term: while one form of a compound may be most stable at one temperature or under a certain pressure, other conditions may exist under which it becomes an unstable form.

X. *Both solution and the formation of new crystalline compounds may result from pressure, and these two operations may take place together; in this way more or less complete interchange of ingredients may take place between the crystalline bodies, and pseudomorphs be formed.*

That most of the pseudomorphic changes, so common in the mineral kingdom, take place at considerable depths from the surface there seems no room to doubt; and in all these cases it may be inferred that pressure is one of the determining conditions of the action.

The effects of these pseudomorphic changes in transforming vast rock-masses into others of totally different composition—such as limestone into dolomite, chalybite, or silica—has long been familiar to geologists; and modern microscopical methods have enabled us to trace the progress of these changes from their earliest beginnings to their complete consummation.

Without entering further into this very wide question, I may mention that Mr. G. F. Becker has lately published the full details of his studies of the Coast-Ranges of California, and that these tend to prove that, in comparatively recent geological times, vast masses of rock in that district have had their substance replaced in some cases by silica, and in others by serpentine; the changes sometimes taking place over considerable areas. These conclusions, arrived at by the officers of the U.S. Geological Survey, if fully established—and there appears to be no room for doubt as to their general accuracy—are not less interesting and suggestive than they are novel and startling.

XI. *When, as the result of dynamical pressures, the crystalline constituents of rocks are brought into close contact, chemical affinity comes into play between them, and new mineral species result from the reactions that take place. This operation is facilitated, when, as a consequence of internal strains, differential movements are set up within the rock-mass, and rubbing or sliding contacts between its particles are brought about.*

Chemists are acquainted with many examples of che-

mical action following from the simple bringing into close contact of molecules. In the union of gases, when they are condensed by platinum-black, and even in the light rubbing of a safety-match on the match-box, we have illustrations of such phenomena.

Spring has shown that, when powdered metals are mixed together and subjected to great pressures, union takes place between them, and alloys are formed. When dry anhydrous salts are similarly treated, double decomposition takes place, and new compounds are formed.

Prof. Thorpe has shown that dry anhydrous salts may be made to react with one another by being simply rubbed together in a mortar; and both Mr. Hallock and Prof. Spring are agreed as to the intensification of action which occurs when rubbing or sliding movements—attended with necessary multiplication of points of contact in compressed bodies—takes place.

Lastly, it may be pointed out that Spring has recently shown *time* to be a very important factor in such changes, by allowing slow diffusion to take place at the surfaces of contact.

That the rocks known as "crystalline schists and gneisses" have had their peculiar characters produced by "internal differential movements," resulting from "enormous irregular pressures," was clearly recognized by Poulett-Scrope, Darwin, Naumann, and Sharpe long before the researches of physicists and chemists had supplied us with the explanation of the phenomena. Modern petrography has confirmed and illustrated these conclusions, enabling us to study the actual stages of the processes of change by which, through the reaction of the constituent minerals of a rock under pressure, the whole mass resolves itself into a completely different mineral-aggregate. The labours of Lossen in the Hartz, of J. Lehmann in Saxony, and of H. Reusch in Norway, have been of especial value in establishing these important conclusions.

As an illustration of this kind of action, we cannot, perhaps, do better than take the case of a rock (gabbro) consisting of three somewhat unstable constituents (see Fig. 2), labradorite (A), pyroxene (B), and olivine (C). In

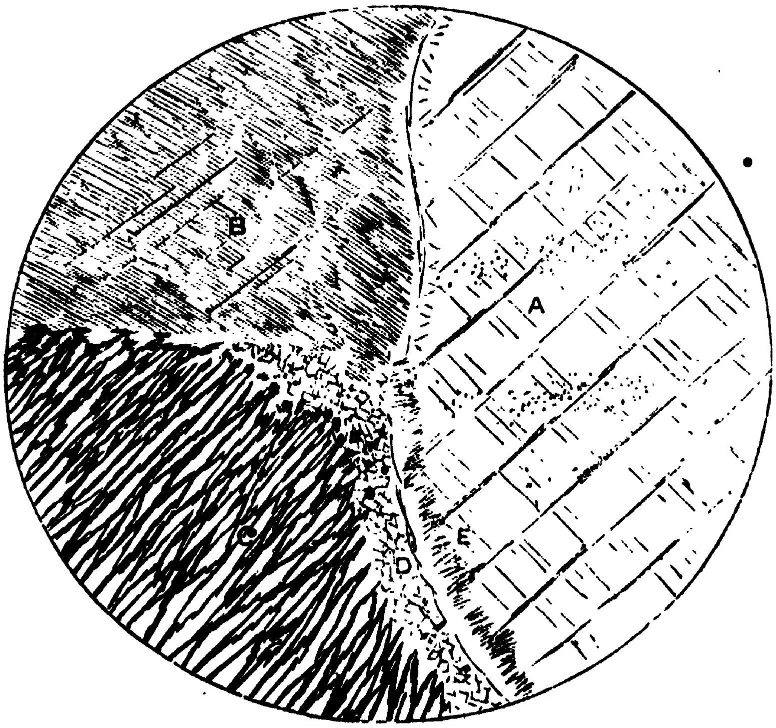

FIG. 2.

the rock from which the figure has been taken, there are clear evidences of its having been subjected to deforming stresses. Where the olivine, the least stable of the three minerals, is in contact with the labradorite, the silicates of which they are composed have reacted upon one another. The result is seen in the formation of a zone between them, consisting of entirely new minerals—a pyroxene (D), and a hornblende (E). Similar changes, but not so strongly marked, are seen to be in progress between the olivine and the pyroxene, and between the pyroxene and the labradorite.

By carefully selecting and studying a series of specimens from the same rock-mass, every step in the metamorphosis of a rock may be followed, from incipient changes like those in the case above illustrated, to the final disappearance of every vestige of the original mineral constituents of the rock, and the substitution of new mineral species.

XII. *When internal strains and differential movements affect a mass, which is at the same time undergoing recrystallization, the forms and relations of the crystalline particles that build up the new rock may be greatly modified by the action of the mechanical forces.*

That perfect rest is a condition upon which well-developed crystallization depends, is a fact too well known to need dwelling upon here. That very small mechanical causes, such as the presence of foreign bodies, or the existence of rough surfaces, may determine the size and position of crystals in a solidifying mass, is also a fact familiar to every chemist. By stirring or similar movements carried on within a crystallizing mass, granulation, or the formation of a number of small imperfect crystals, rather than of large and well-developed ones, is brought about; as in the well-known Pattison's process for desilverizing lead.

The evidence of perfectly similar actions having taken place in crystallizing rock-masses is everywhere conspicuous; and the results are the same, whether the crystallization occurred in a mass passing from a fluid to a solid state, or in a mass which remained solid during the whole process of recrystallization.

There are two structures which are especially exhibited by rocks that have been subjected to dynamo-metamorphism which seem clearly to have been produced by such causes; these are the structures known as the *granulitic* and the *foliated*.

The *granulitic* structure, which is so well exhibited by the rocks called "granulites," is characterized by the crystals assuming the form of granules, having more or less rounded outlines, and lying in every position; so that, under the polariscope, the mass resembles a fine mosaic. I have shown that well crystalline rock-masses (gabbros), when forced in a molten state through great fissures, assume on their edges, where much friction must have occurred, this granulitic habit, which is sometimes exhibited in a very striking manner (Quart. Journ. Geol. Soc., xlii. 76, &c.).

The foliated structure, so characteristic of schists and gneisses, consists in the separation along nearly parallel planes of leaf-like patches (folia) of the several mineral constituents of the crystallizing mass. Poulett-Scrope, from his study of the viscous lavas of Ponza, Lipari, and Hungary, and Darwin, from his study of the similar lavas of Ascension, were able to show that these rocks, under similar conditions, often assume a *foliated* structure. Perfectly granitic rock-masses, like the syenite of the Plauenschen Grund and the granitite of Aberdeen, sometimes exhibit on their margins a distinctly foliated structure.

It is worthy of notice that both the granulated and the foliated structures are produced in recrystallizing masses that are subjected to internal strains and differential movements. They are equally produced when the mass has been a liquid which has slowly passed into the solid state by the process of crystallization; and when by the processes we have already considered the mass, *retaining its solidity*, has undergone internal molecular rearrangement and recrystallization.

A rock-mass behaves as a viscous body, under slight pressures, when heat and the presence of water have overcome the cohesion of its particles. But the researches of Tresca and Daubrée have shown that, when subjected to sufficiently powerful stresses, the most perfectly solid bodies we know of behave like viscous bodies, and can be made to *flow*.

In the foregoing remarks, my main object has been to show how far the physical and chemical principles, which have been established by actual experiment, are capable of explaining the phenomena observed by the geologist in studying the earth's crust. I have especially avoided invoking any causes which must be regarded as hypothetical.

Some of the actions relied upon as explaining the origin of the great features of the rock-masses which compose the earth's crust may seem at first sight small and even insignificant. But the great lesson taught by modern geological science is that such small forces, operating upon enormous masses of matter during vast periods of time, are capable of effecting the most stupendous results.

In speaking of *statical* pressure, I have not treated it as an agent of change, like heat or electricity, but simply as a condition under which these agents operate—one which may profoundly modify or control their action. Such pressure, too, may produce great effects by causing a closer contact and consequent chemical action between the molecules of a fluid made to penetrate a solid, or between the molecules of two solids forced into more perfect contact. Statical pressure may, further, prevent the escape of volatile materials even under extreme temperatures, and these substances, as in the case of the "mineralizers" of the French chemists, may exercise important influences on the solids or liquids within which they are retained.

Dynamical pressure, especially when it results in differential movements in a mass, can certainly do all that is effected by statical pressure, and perhaps something more. That such motion is converted into heat there can be no doubt; and some geologists, like the late R. Mallet and Prof. Prestwich, have argued that the heat so produced must have played an important part in the work of metamorphism. But considering the slowness with which the earth-movements have probably taken place, and the opportunities for the dissipation of this thermal energy, it may be regarded as at least doubtful if at a particular point in the rock-mass the temperature could ever have been raised to such an extent, that any very important part of the work of metamorphism ought to be ascribed to it. In the same way, we may, perhaps, regard the suggestion of Mr. Sorby that, during great earth-movements, mechanical energy is directly converted into chemical energy, as one in favour of which no convincing evidence has as yet been adduced.

It is at least conceivable that the realm of excessively *high* pressures is one in which phenomena may be displayed which are as anomalous as those exhibited under extremely *low* pressures—the high *vacua* of Mr. Crookes. But until such effects have been demonstrated by actual experiment, it is unwise to invoke their aid in geological hypothesis. My great object, in the remarks I have ventured to offer you this evening, has been to show that, on well-established physical and chemical principles, the phenomena, which are exhibited by rock-masses that have been subjected to great pressures, are capable of satisfactory explanation.

THE UNIFORM PENNY POST.

Of all the jubilees that are now being celebrated, there is none which has had a more beneficial influence on the age than that celebrated last week at the Guildhall, with such success and good management. There are some who deplore the decay of letter-writing, and even a few who regard the penny post as an unmitigated evil, but no one can fail to perceive that the conduct of the great commercial business of this country would have been impossible without cheap postage.

We are not celebrating the penny post. This was proposed in 1659, by one John Hill, an attorney of York—curiously enough a namesake of Sir Rowland's—who showed its practicability and advocated free trade in letter-carrying. He proposed a rate of 1*d.* in England, 2*d.* in Scotland, and 4*d.* in Ireland, as well as 3*d.* per ounce for small parcels.

Nor are we celebrating the invention of adhesive stamps, but the introduction, in 1840, of that great measure which swept away a sliding scale of postage of single letters written on single sheets of paper which varied between 4*d.* and 1*s.*, and a system of franking that had grown, even in the reign of our present Queen, to a most shameful abuse. Envelopes or covers and enclosures involved double postage. If the letter weighed an ounce the rate was quadrupled. A single letter, London to Brighton, cost 8*d.*, to Edinburgh 1*s.* 1½*d.*, to Cork 1*s.* 5*d.*; or if it weighed 1¾ ounces, to Edinburgh 7*s.* 7½*d.*, to Cork 9*s.* 11*d.* The number of letters passing through the post in 1839 was 76,000,000. In 1889, it amounted to 1,600,000,000, and this excludes newspapers, post-cards, books, and parcels. The grand total for 1889 was 2,362,000,000.

It is not too much to say that the transport of this enormous mass of material would have been impossible but for the advent of steam. Railways and steam-boats have led to the possibility of the uniform post. Telegraphs have made its administration practical and simple. Without these practical applications of science its success would have been impossible. Pack-horses, mail-coaches, and sailing-vessels, would have failed to transport mails with the celerity, trustworthiness, and regularity, that are the essentials of a true postal service.

The Stuarts made the Post Office a monopoly of the Crown; and the Commons, who in Charles's day denounced the establishment of the monopoly, promptly proceeded by Cromwell's soldiers to put down John Hill and his free trade in letters. It has remained the monopoly of the State, and its work is well done, but this is due to the fact that it is so well supervised by the public itself, every member of which is interested in its well-working. If the breakfast table is not garnished with the expected letters, if any abuse, want of accommodation, or delay occurs, the press or the House of Commons soon wants to know the reason why, and the remedy is at once applied. In fact, the public is the master and the postal service knows it. In no service in the world can there be found more zeal, energy, and attention. The rewards are not quite so evident. Although this is the jubilee year, Post Office names were conspicuous by their absence from the Queen's Birthday honours, and even such ardent reformers as Mr. Henniker Heaton, with an ignorance that is surprising, speak in contemptuous terms of the unimpressionable mind of the red-taped official.

The most scientific branch of the Post Office is unquestionably the telegraphic. Many fears were entertained that its efficiency would deteriorate under the supposed chilling influence of Government monopoly, but these fears have not been realized. Facilities have been increased, business has been developed, improvements have been introduced, new processes have not only been adopted but originated, and our Postal Telegraph Department unquestionably holds the most prominent position in the world at the present moment. The number of messages, which in 1869, the year before the transfer, amounted to 6,000,000, now reaches over 60,000,000. Duplex, quadruplex, and sexuplex methods have been made practical. The automatic system of Wheatstone,

which its ardent inventor hoped would work well at 120 words, now works equally well at 600 words a minute.

The telephone, owing to mismanagement and the operation of our Patent Laws, has not received much development in England yet; but with the expiry of the patents at the end of this year it is hoped that every post-office will become an exchange, and the business of telephony will flourish as well in England as it has in Sweden and Norway and some of the smaller States in Europe. Competition and free trade will certainly tend to bring this marvellous and beautiful apparatus within the sphere of every domestic circle.

It is marvellous how science is rapidly becoming a household god. The electric light, bells, and telephones must prompt all to some knowledge of electricity. Ventilation, sanitation, pure water, warming apparatus, lead to a knowledge of other scientific principles. The laws of Nature are rapidly but surely becoming as familiar in our mouths as household words.

PENDULUM ELECTROMETER.

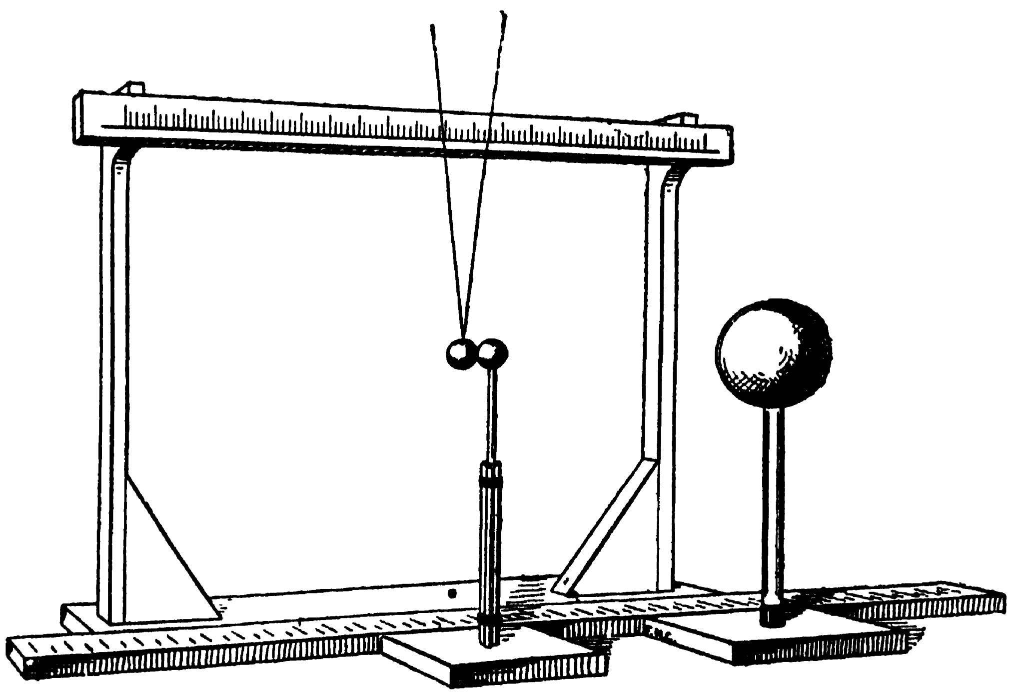
IN order to obtain an inexpensive apparatus by which the nature of electrostatic measurements could be clearly presented to students, and the measurements carried out before a class with ease and despatch in absolute units, Prof. Mayer, of the Stevens Institute of Technology, of New Jersey, has arranged the apparatus shown in the accompanying figure.

It consists of a gilt pith ball of 1 cm. radius, made of pieces of pith cemented together, and suspended at a distance of 364 cm. from the ceiling by a very fine silk fibre passed through a small staple driven into the ball. The ends of the fibres are attached to the ceiling at a distance of 52 cm. apart, and arranged so that the suspended ball can be raised or lowered, until it is at the same height as a brass ball, also of 1 cm. radius, supported on a glass rod, coated while hot with paraffin wax. A force of 1 dyne acting on the suspended ball deflects it through 13·3 mm., and, as 2° deflection was the maximum employed, the scale was inclined to the horizontal so as to coincide with the chord of an angle of 2°.

If a charge be given to the two small balls when in contact, and when therefore it will divide equally between them, the charge on either in *absolute electrostatic units* equals

$$D\sqrt{\frac{d}{\cdot 33}},$$

where d is the deflection in centimetres of the pendulum from the vertical, and D the distance in centimetres between the centres of the two balls.



To test the sensitiveness of the apparatus, the ball on the stand was placed at various distances from the suspended one, and the force between them observed. The law of the inverse squares was found to be verified with an error of less than 1 per cent. when D was over 5¼ cm. Next the gradual diminution of the deflection when the brass ball on the stand was in a fixed position was used to measure the rate of loss of charge, and it was found that the measured leakage to earth was proportional to the measured charges with a considerable degree of accuracy in several experiments, and with a maximum error of 20 per cent. in the most discordant experiments. Then the pendulum electrometer was used to measure the electric distribution over the surface of a cylinder, a proof plane being employed to convey the charge from different parts of the surface of the cylinder to the pendulum electrometer, and results were obtained closely agreeing with those obtained by Coulomb. Lastly, the potential of the large sphere was experimentally determined in absolute electrostatic units for different charges given to it.

NOTES.

WE are glad to learn that the President of the French Republic has conferred on Prof. Sylvester and Prof. Cayley the "Decoration d'Officier de la Légion d'Honneur." This honour has been granted in consequence of a request addressed to the French Minister of Foreign Affairs by the President and other members of the Academy of Sciences.

LORD RAYLEIGH has been elected a corresponding member of the Imperial Academy of Sciences in Vienna.

THE French Association for the Advancement of Science will hold its nineteenth meeting at Limoges from August 7 to 14. Various English men of science have been invited by the Bureau of the Association to attend the meeting, and they are asked to let their decision be known before July 1. Those of them who accept the invitation will be the guests of the Municipality of Limoges.

THE Queen has been pleased to approve of the grant of Civil List pensions to Miss Charlotte, Ruth, Margaret, and Rose,

daughters of the late Rev. M. J. Berkeley, F.R.S. A Civil List pension has also been granted to Mrs. Wood, widow of the Rev. J. G. Wood, the well-known popular writer on natural history.

Dr. James Clark, M.A. (Edin.), Ph.D. (Tübingen), Royal Exhibitioner and Associate in Botany, Prizeman in Geology (Edinburgh University), has been appointed Professor of Natural History in the College of Agriculture, Downton, Salisbury. Dr. Clark has recently been employed on important work in the Natural History Department of the British Museum, and is the author of several papers on geology and biology.

A Chair of Mechanical Engineering is about to be established in connection with the University College of South Wales and Monmouthshire, Cardiff; and the authorities of the institution are already looking about for a suitable professor. A lectureship in mining engineering will shortly be founded at the same College, and electrical engineering is also to receive attention.

The Annual Congress of the British Archæological Association will be held at Oxford in the second week of July.

An important International Photographic Exhibition will be held in Vienna in April next year. The *Photographic News* says it is intended that only comparatively recent work, and that of the best kind, shall be shown. A jury of artists and photographers will decide as to the admission of pictures. The Exhibition will be held in the Imperial Austrian Museum of Art and Industry.

Mr. Thomas Layton, F.S.A., of Kew, who has for many years been engaged in forming a museum of the prehistoric antiquities of his district, has lent to the British Museum a fine series of bronze swords, spears, and axes, all found in the River Thames between Richmond and Battersea. The loan is shown in a case by itself.

A Scientific and Industrial Exhibition was to be opened at Kazan on May 27. It will contain exhibits from Eastern Russia, Siberia, Central Asia, and the Caucasus, and promises to be of great interest to ethnographers.

Dr. Adolf Strubell, of Frankfort, who started on a journey of zoological research in India in March 1889, is now in Java making scientific collections, which he intends to present to the Senckenberg Museum of Frankfort.

The celebration of the six hundredth anniversary of the foundation of the University of Montpellier has been most successful. All the great technical schools of Paris and the French provinces were represented, and deputations from many foreign Universities were present. The proceedings began on May 22, when there was a great reception in the University hall. M. Chancel, the Rector, welcomed the guests, and Prof. Tedenat sketched the history of the University and its most celebrated professors. On the following day M. Carnot arrived. The delegates of foreign Universities, followed by those of the great French schools, marched from the University to the Prefecture to be presented to the President of the Republic; and, if we may judge from a description by a correspondent of the *Times*, the procession must have been a remarkably interesting spectacle, the French and foreign professors being in robes of the most varied colours. The pavement and balconies along the route were crowded by men, women, and children. After the ceremony at the Prefecture the company proceeded to a park overlooking the town, commanding a view of the Cevennes on one side and the Mediterranean on the other. Several speeches were delivered under an awning. The Rector of the University thanked the President for having honoured the celebration by his presence. M. Croset gave a history of the University, and dwelt on the great trade of Montpellier in the Middle Ages, and its relations with the Arabs and Jews. Its most flourishing period, he said, was from the twelfth to the fourteenth century, and Petrarch spoke of it as a kind of ideal University. It made special progress in studies based on the observation of nature. The delegate of Bologna, the most ancient University represented, thanked M. Carnot for his reception of the foreign delegates. M. Bourgeois, Minister of Education, in a much-applauded speech, said the Government recognized the justice of the desire expressed by Montpellier and the other great schools to resume the name of University and the privileges associated therewith, and the question would shortly be discussed in the Chamber. We may specially note that the later proceedings included the presentation of an address by French men of science to Prof. Helmholtz, who represented the University of Berlin.

The Königliche Physikalisch-Oekonomische Gesellschaft of Königsberg, one of the oldest societies of its kind, recently celebrated its centenary. It met first in Mohrungen, but in 1792 was amalgamated with the Economical Reading Institute of Königsberg, and thereafter bore its present name. In its earlier years it dealt chiefly with rural economy and agriculture. Later on, questions of natural science came more to the front, partly under the influence of Karl Ernst von Baer, the most illustrious name in the Society's annals. Still later, the Society had an anatomist of note among its members, Heinrich Rathke, who did good work in the same field as von Baer.

Dr. T. A. Hirst, a former President of the Association for the Improvement of Geometrical Teaching, has presented to the Association, for its library, a valuable gift of forty volumes on geometry. The Association has also acquired by purchase an interesting collection of about twenty-five older text-books, including the "Treatise on Algebra" by Saunderson, the blind Lucasian Professor, and Stirling's "Methodus Differentialis."

On Wednesday, May 21, a public meeting was held at the Mansion House "to promote the national work undertaken by the committee for testing smoke-preventing appliances." The Lord Mayor presided. Lord Derby proposed a resolution approving the objects of the committee. He thought that the diminution of smoke, and its necessary accompaniment dirt, was a matter which concerned everyone, except those who were fortunate enough to live away from great towns. Indifference was the real difficulty which they had to encounter, but in England anything which came to be recognized as a want was eventually supplied. The expenditure of fuel in creating dirt—for that was what it came to—was a waste of fuel itself, and the injury caused to property was not inconsiderable. He believed that more than three-fourths—he would say something like nine-tenths—of the smoke from collieries and factories was absolutely preventable, though some trouble and outlay would be required. Possibly more stringent legislation would be needed, but let them first try the experiment of enforcing the laws which they already had. Lord Howard of Glossop seconded and Prof. Chandler Roberts-Austen supported the resolution, which was carried unanimously. On the motion of Sir Henry Roscoe, M.P., seconded by Earl Fitzwilliam, and supported by Alderman Bowes (Salford), a resolution was passed in favour of the raising of a fund to meet the expenses of the work.

Some interesting explorations have just been made in connection with the famous Adelsberg Cave. The Vienna Correspondent of the *Daily News* says that various citizens of Adelsberg, wishing to ascertain whether the Ottoker Cave, discovered a year ago at some distance from Adelsberg, was in any way connected with the great cave, followed the course of the subterranean river Poik. It was known that forty years ago a party of explorers had their progress barred by a large lake, and the present adventurers therefore carried with them a boat.

Having successfully crossed the body of water mentioned, they came to lofty galleries through which the river flowed. It was possible to walk on the banks of the stream, but at intervals it expanded into small lakes, and the boat had to be used. At last the gallery branched into two corridors, one of which the stream rendered impassable, while the other was high and quite dry. The boat was dragged up, and the party proceeded. After crossing a fourth lake, the largest they had met, they found that the Ottoker Cave had been reached. The journey through the galleries lasted six hours. The explorers saw that they had by no means penetrated to the remotest parts of the grotto, and there is evidently still a wide field for discovery.

ACCORDING to a telegram sent through Reuter's Agency from New York, a slight shock of earthquake was felt at Utica and at other points in the northern portion of New York State on May 25. The disturbance was felt more severely in Montgomery County. At Little Falls the shock was sufficiently strong to cause dishes and other similar articles to rattle, and subterranean rumblings were heard, while at Fort Hunter the buildings were so shaken that beds were moved and their occupants awakened. No damage was done.

ANOTHER telegram, sent through Reuter's Agency from Constantinople on May 26, tells of the destruction of an Armenian village by an earthquake. The village was Kayi, in the district of Refahie. Mineral springs spouted from the crevices made in the ground, and flooded the fields. There was no loss of life, as two days previously subterranean rumblings were heard, and cracks appeared in the ground, in consequence of which the Caimakan of the district ordered the inhabitants to leave the village.

ON Sunday last an influential meeting was held in Madrid, at the official residence of the Prime Minister, to prepare the way for the celebration, in 1892, of the four hundredth anniversary of the discovery of America by Columbus. The meeting selected a Grand Committee, which will act in concert with the Spanish Government and the Royal Commission appointed some time ago, and presided over by the Duke of Veragua, a lineal descendant of Columbus, and the present Minister of Public Works. The Madrid Correspondent of the *Daily News* says that the most eminent among Spanish statesmen, as well as artists, writers, men of science, and military men, will assist on the organizing committees. It is proposed that the centenary shall be celebrated, if possible, by an Exhibition at Madrid. Vigorous preparations are also being made at Genoa for the suitable commemoration of the same great event.

THE Danish Admiralty has ordered systematic hydrographical observations to be made all round the Danish coast. They began on May 1, and are to be continued regularly once a month on all lightships and on five movable stations. The object of these observations is to obtain detailed data concerning the ichthyological and meteorological conditions of the Danish seas. Special apparatus has been constructed by Captain Rung for the measurement of the percentage of salt in the sea-water.

WE learn from *Science* that, at a recent meeting of the American Meteorological Society in Washington, resolutions were adopted "favouring the recognition of the eminent services of American electricians by perpetuating their names in the nomenclature of electrical units." At the Electrical Conference to be held in America in 1892, it will be proposed that the name of Joseph Henry—or some modification of it—shall be given to the unit of self-induction, "he having been the first to investigate that phenomenon, and his investigations having been more complete than those of other electricians before or since."

THE temperature of snow at different depths has been investigated by Signor Chistoni. He finds that the variations in temperature of the lowest layer, next the ground, are extremely small, whilst the uppermost layer has often considerably higher temperature (as much as 10° C. at times). The temperature minimum of the air-layer next the snow was always lower than that of the uppermost snow-layer, while an air-layer about 20 inches above the snow had a higher temperature than the layer 1·2 inches above the snow.

DR. J. HANN communicated to the Academy of Sciences at Vienna, on April 17, a memoir on the high air-pressure of November 12–24, 1889, in Central Europe, together with remarks upon high-pressure areas generally. As this anticyclone lay nearly the whole time over the Alpine district, observations could be made at various stations up to a height of above 10,000 feet. Dr. Hann found (1) that the high pressure extended to more than three kilometres above sea-level; (2) that at this altitude the relative warmth was as great as at a height of one kilometre, while the usual depression of temperature of winter anticyclones was limited to a few hundred feet above the earth; (3) that great dryness prevailed in the higher strata of the air. The author finds in these results a cogent reason for concluding that in barometrical maxima the air has a descending motion, and that the conditions of pressure are not explained by conditions of temperature, but are a consequence of the movement of the air. The temperature conditions are dependent upon the movements of the anticyclones, in the same way as the dryness of the air, and the clearness of the sky. In another section of the paper he investigates the vertical distribution of temperature in a barometrical minimum. During one instance, on October 9–10, 1889, he found that the temperature on the summit of the Sonnblick was lower than during the barometrical maximum above quoted. Until the establishment of mountain stations, the temperature was assumed to be one of the chief causes of the form of motion of cyclones and anticyclones, but future inquiries must take into account that up to at least four or five kilometres the temperature of the centre of an anticyclone may be, and probably always is, higher than in the centre of a cyclone.

IN a recent number of the *Zeitschrift für Schul-Geographie*, Mr. H. Habenicht has written an article on the causes of the cyclones of the North Atlantic. The author points out that, if the globe were covered with water, the general circulation of the air would be very regular, without local depressions and steep barometric gradients, and he refers to the contrast of the systems prevailing, *e.g.* between the South Pacific and the North Atlantic. He finds the explanation primarily in the obstruction offered to the regular courses of the winds by the great continents to the east and west of the Atlantic; and, secondly, in the constant barometrical maxima over the continent in winter and in the neighbourhood of the Arctic regions.

THE Massachusetts Institute of Technology, Boston, has issued the twenty-fifth annual catalogue of its officers and students, with a statement of its courses of instruction and a list of its alumni. The courses of study include the physical, chemical, and natural sciences and their applications; pure and applied mathematics; drawing; the English, French, German, and other modern languages; history; political science; and international and business law. It is claimed that these studies and exercises are so arranged as to afford a liberal and practical education in preparation for active pursuits, and a thorough training for most of the scientific professions.

IN the entomological part of the forty-first Annual Report of the trustees of the New York State Museum of Natural History, lately published, reference is made to the statements which have been advanced as to the long imprisonment of beetles within furniture. The writer suggests that when such cases occur the condi-

tions may bring about a lethargic state, in which respiration and accompanying phenomena are almost or entirely suspended through the complete exclusion of air (a hermetic sealing) by the rubbing, oiling, varnishing, or other polishing which the furniture has undergone. As an instance of prolonged vitality, he quotes an extract from the third Report on the insects of New York, by Dr. Fitch. In this passage Dr. Fitch says:—"In 1786, a son of General Israel Putnam, residing in Williamstown, Mass., had a table made from one of his apple-trees. Many years afterwards the gnawing of an insect was heard in one of the leaves of this table, which noise continued for a year or two, when a large, long-horned beetle made its exit therefrom. Subsequently, the same noise was heard again, and another insect, and afterwards a third, all of the same kind, issued from this table-leaf—the first one coming out twenty, and the last one twenty-eight, years after the tree was cut down." The evidence before Dr. Fitch convinced him that the insect was the longicorn beetle *Cerasphorus balteatus*, now known as *Chion cinctus* (Drury).

THE *American Naturalist* quotes from the *Salem Register* an extract from which it seems that the museum of the Peabody Academy of Science of Salem, Mass., has lately been enriched by a fine collection of objects illustrating the art and ethnology of Japan. This has been formed by Prof. Edward S. Morse, who some time ago spent several months in Japan. The catalogue of Japanese accessions enumerates 691 specimens, the most conspicuous objects being life-sized figures, representing different classes of the community. These models were all made for the museum, and are the best that have ever been brought to America. The collection also includes many fine old swords, sets of tools, and pictures illustrating various trades and professions.

SOME curious electrical phenomena were lately observed (according to a writer in the *Chemische Zeitung*) in a stearin and ceresin manufactory in Italy. One evening four vats of white ceresin (which is a paraffin got from ozokerit), containing about 500 kg. each, were being stirred to cool. When the point of solidification was nearly reached, the electric light of the place accidentally went out; and, to the surprise and alarm of the rather ignorant workmen, the mass of ceresin was observed to give pale sparks on the slightest motion. If the hand was brought near, loud sparks nearly two inches long were obtained. The phenomenon lasted over half an hour.

A VALUABLE collection of Tibetan medical works and drugs has been brought by M. Ptitsyn from Transbaikalia. He has also collected most interesting information as to the courses of study at the Buddhist *lamas'* University at the Gusinoie Ozero Monastery in Transbaikalia. The curriculum lasts ten years, the first four of which are devoted to the study of the Tibetan and Mongol languages, to religious service, and to practice in drawing and various handicrafts. The next three years are given to medicine. During the first of these three years the pupils learn by heart the five volumes of the chief Tibetan hand-books of medicine, and the names of the drugs. The next two years are given to the study of therapeutics and surgery. The students also visit the Urga High School to follow the courses of the more renowned Tibet *lamas*, who come to Urga on purpose. The eighth year is given to astronomy and astrology, and the last two to philosophy and theology. Medicine is studied only by those who wish to devote themselves to the medical profession, and the courses of astronomy, astrology, philosophy, and theology are followed only by the best pupils. The chief (printed) medical work of Tibet is the "Rodijachava," or "The Tale of the *Curkhan* Otochi (god of Medicine) about what formerly was," a copy of which was secured by M. Ptitsyn. The Tibet medical authorities recognize 101 fundamental diseases, and M. Ptitsyn gives the names of 429 elements of drugs used by the Buddhist physicians. He notices that of the 101 diseases only two (paralysis and a kind of influence of the planets) are attributed to a mythical origin, and that of the 429 drugs only three have a similar origin (the bones of a dragon, the horns and the skin of the unicorn). The remainder are chiefly herbs, seeds, fruits, roots, and flowers, and partly mineral matters. They are all bought in Chinese drug-shops, except quinine, which is bought in Russia. M. Ptitsyn was allowed to visit one of the drug-shops, and found all drugs kept in order in separate drawers. He has brought to St. Petersburg samples of 202 different drugs, which will be analyzed at the Medical Academy.

SOME sea-urchins are known to live in cavities in rock. And the diameter of the cavity is often wider than that of the entrance, so that the animal could not leave its home or be taken out without injury. On the French coast of Croisic (Lower Loire) may be seen thousands of urchins thus ensconced in the granite rock, which is rich in felspar and quartz. The animals, it is not doubted, make and widen the holes for themselves; but the question how has not been satisfactorily answered. Chemical solution of the rock seems excluded, considering both the nature of the latter, and also that no acid which could be thus used has been proved to exist in the urchin. The matter has been studied lately by M. John, and in an inaugural dissertation (*Arch. f. Naturges.*) he explains the effects by mechanical action. With the so-called "lantern of Aristotle" the animal probably bites the rock; the sucker feet are also attached, and a rotatory motion is imparted to the body, the prickle points, with the lantern, gradually wearing down the surface. These cavities afford a shelter to the urchins against the action of the waves. An attempt is made to conceal them by means of mussel and other shells. The rocks in which the cavities occur are in general thickly covered with calcareous Algæ. It has been thought that possibly these decompose the rock, and so facilitate the work of the urchins. M. John, however, finds no such chemical relation, but atmospheric agencies, he considers, may help the work of boring. A number of other animals are known to penetrate rock, and it is supposed that they do it also in a mechanical way. Recently, M. Forel described to the Vaudois Society of Natural Sciences how in the hard limestone of Constantine, Algiers, *Helix aspera* was found in holes 4 to 5 inches in depth.

IT has been hitherto impossible, by the most careful and subtle methods, to produce absolutely pure water. Such water, it is thought, would have no conductivity for the galvanic current; but, as a matter of fact, there is always a measurable conductivity, which, in glass-vessels *e.g.*, gradually grows from day to day, through glass being dissolved. It has been lately observed by Herr Pfeiffer (*Wied. Ann.*) that water purified as much as possible, and standing only a short time in contact with the air, showed next day a continuous decrease of conductivity, which gradually disappeared, giving place to the normal unavoidable increase. After testing various explanations of this by experiment, he came to the conclusion that the true explanation is micro-organisms coming into the water, and absorbing the conducting substances present. On this assumption such organisms would appear to have an almost absolute power of absorption, something like that of sulphuric acid for water-vapour.

MR. L. UPCOTT GILL has issued the first part of a volume entitled "British Cage Birds," by Mr. R. L. Wallace. The work will be completed in 15 parts, and will contain directions for breeding, rearing, and managing the various British birds that can be kept in confinement. Mr. Gill has published also the first part of "The Canary Book," by the same author. Both works are illustrated with coloured plates and wood-engravings.

IN the new number of the *Internationales Archiv für Ethnographie*, Hermann Strebel continues his paper on a peculiar kind of stone object, found in Mexico and Central America, which is generally supposed to have been used in connection with the sacrifice of human victims. It is fashioned in the shape of a yoke or bow, and enriched with sculpture. Herr Strebel shows that it was worn as a mark of honour by persons of high rank. The sculpture was, he believes, of a symbolical character. Dr. L. Lewin, of Berlin, contributes an interesting paper on betel-chewing, adding fresh information to that which he brought together in a previous article. M. de Clercq gives some notes (in Dutch) relating to New Guinea, and Herr H Vos deals with the area of anthropophagy on the Asiatic continent.

THE Leicester Literary and Philosophical Society has issued the third part of the second volume of its Transactions (new quarterly series). Among the contents are the abstract of an address, by Prof. Flower, on pygmies; a paper on spiders, by the Rev. W. Agar; and a contribution to the pterylography of birds' wings, by W. P. Pycraft.

WE have received Part 20 of Cassell's "New Popular Educator." It is carefully illustrated, and contains maps of Eastern Australia and New Zealand.

MR. JOHN WHELDON has issued a catalogue of zoological works, and papers, transactions, and journals relating chiefly to anatomy and physiology. A catalogue of works on astronomy, magnetism, and meteorology has been issued by Messrs. Dulau and Co.

PYRAZOL, $C_3H_4N_2$, the fundamental base of a rapidly growing series of compounds, has been synthesized by Prof. Balbiano, of Messina, from epichlorhydrin and the recently isolated hydrazine hydrate (*Berichte*, No. 8, p. 1103). Pyrazol is a pentagonal closed chain compound, which may be represented

$$\begin{array}{c} CH-CH \\ CH \qquad N \\ NH \end{array}.$$

The reaction between epichlorhydrin and hydrazine hydrate is a somewhat violent one, a considerable amount of heat being generated. It appears to take place in the manner indicated by the following equation:—

$$\left.\begin{array}{l} CH_2 \\ | \\ CH \end{array}\right> O \\ \begin{array}{l} | \\ CH_2Cl \end{array} + 2N_2H_4 . H_2O = C_3H_4N_2 + N_2H_4 . HCl + 3H_2O + H_2.$$

Equal weights of epichlorhydrin and hydrazine hydrate, which latter is a liquid boiling at 119° C., are cautiously mixed in a flask, to which is immediately fitted a reflux condenser. The reaction completes itself in 3–4 minutes without any external application of heat. When the reaction is at an end, and the last trace of the epichlorhydrin has disappeared, the flask and contents are heated in a water-bath for 25–30 minutes. After allowing to cool, a quantity of zinc chloride equal to that of either of the reagents is added, in order to facilitate the splitting off of water. The whole is afterwards again heated for an hour over the water-bath. The yellow waxy mass so obtained is then mixed with 300–400 c.c. of water for every 10 grams of either reagent employed, and the mixture distilled in steam. Pyrazol and ammonia distil over in the steam together, and, in order to separate the pyrazol, the distillate is treated with a solution of mercuric chloride, which produces a mixed precipitate of the mercury compound of pyrazol and mercurammonium chloride. The precipitate is suspended in water, decomposed with sulphuric acid, and the solution of pyrazol hydrochloride and salammoniac evaporated to the crystallizing point on the water-bath. The residue is then decomposed by potash, and the pyrazol extracted by ether. Upon evaporation, pyrazol is obtained as a mass of hard colourless needles. The crystals of pyrazol are readily soluble in cold water, with production of a neutral solution. They possess an odour very similar to that of pyridine. They melt to a colourless liquid at 69·5°–70°, and the liquid boils at 186°–188°. The aqueous solution gives a white precipitate with mercuric chloride solution and with an ammoniacal solution of silver nitrate. In all these respects the pyrazol thus prepared from epichlorhydrin and hydrazine hydrate is identical with a substance of the formula $C_3H_4N_2$ prepared some little time ago by Buchner by heating the methyl ether of acetylene-dicarboxylic-diazoacetic acid. A concentrated hydrochloric acid solution of pyrazol gives, with platinum chloride, a precipitate of lustrous yellowish-red needles of pyrazol-platinate $(C_3H_4N_2 . HCl)_2PtCl_4 . 2H_2O$. When this salt is heated to 205°, the colour changes to straw-yellow, and remains permanent up to 250°. The yellow substance is a definite compound, insoluble in water, and possessing the composition $\left.\begin{array}{l} C_3H_3N_2 \\ C_3H_3N_2 \end{array}\right> PtCl_2$. It is formed from pyrazol-platinate by loss of two molecules of water and four molecules of hydrochloric acid.

THE additions to the Zoological Society's Gardens during the past week include two Beatrix Antelopes (*Oryx beatrix* ♂ ♀) from Arabia, presented by Colonel Ross; a North African Jackal (*Canis anthus*) from North Africa, presented by Captain Hay; a Common Paradoxure (*Paradoxurus typus*) from India, presented by Mr. C. Armstrong King; a Vociferous Sea Eagle (*Haliaëtus vocifer*), a White-crested Tiger-Bittern (*Tigrisoma leucolophum*) from West Africa, presented by Mr. J. B. Elliot; a Mexican Guan (*Penelope purpurascens*) from Mexico, presented by Mr. J. W. Dawe; two Common Kingfishers (*Alcedo ispida*), British, presented by Mr. T. E. Gunn; a Tawny Owl (*Syrnium aluco*), British, presented by the Hon. C. Parker; two All-green Snakes (*Philodryas viridissimus*), two Natterer's Snakes (*Thamnodynastes nattereri*), two Merrem's Snakes (*Liophis merremi*), a Chequered Elaps (*Elaps lemniscatus*) from South America, presented by Mr. A. C. Derrett; a Barraband's Parrakeet (*Polytelis barrabandi*) from New South Wales, a Brush Turkey (*Talegalla lathami*) from Australia, deposited; an Eland (*Oreas canna* ♂), bred in France, two Diademed Jays (*Cyanocitta diademata*) from Mexico, two Temminck's Tragopans (*Ceriornis temmincki* ♂ ♀) from China, purchased; two Persian Gazelles (*Gazella subgutturosa* ♂ ♂), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

OBJECTS FOR THE SPECTROSCOPE.

Sidereal Time at Greenwich at 10 p.m. on May 29 14h. 29m. 9s.

Remarks.

(1) There are no very bright nebulæ which come to the meridian near 10 o'clock during this week, but the one given is probably one of the brightest. The General Catalogue description is: "Bright, pretty large; round; pretty suddenly brighter in the middle; barely resolvable (mottled as if with stars); a 12th magnitude star in *nf* quadrant." The spectrum has not been recorded.

(2) According to Vogel and Dunér this star has a magnificent

spectrum of Group II. All the bands 1–9 are plainly visible; they are wide and dark throughout the whole length of the spectrum. The chief observations required of such a star as this are direct comparisons with the bright carbon flutings, as their existence in stars of the 2nd group is still not generally accepted, although Dr. Copeland demonstrated it most conclusively in the so-called "Nova" Orionis. Our ideas of the constitution of this class of stars must turn almost entirely on this point; if the bright flutings exist, the stars, like comets, must consist of discrete masses.

(3) This is a star of the solar type (Vogel). The usual observations are required.

(4) The spectrum of this star is one of Group IV. The usual additional observations are required.

(5) This highly interesting variable will reach a maximum on May 30. The magnitude at maximum varies from 4 to 6·5, whilst that at minimum is below 13. The change of luminosity is therefore enormous, and it is obvious that many of the explanations offered for different kinds of variables, such as variation of spotted area, are quite insufficient for a case like this. The period is about 406 days, but it appears to be shortening. The spectrum is a magnificent one of Group II., and near the maximum last year Mr. Espin noted the presence of bright lines, amongst which the line D_3 was very bright. In future observations, the bright carbon flutings should also be carefully examined, as it seems very probable that, if they exist, they will brighten along with the lines of hydrogen and D_3. If the principal fluting, near *b*, be sufficiently bright, the 2nd maximum of the fluting may be bright enough to be measured. The collision theory of variability seems to explain this class of variable in every detail, even to the lengthening of the period, for the retardation which the secondary swarm would undergo at maximum must inevitably in time lengthen the period.

The Spectrum of Comet Brooks (*a* 1890).—On the evenings of May 21, 22, and 23, I made some observations of this comet which may not be without interest. On the 21st the appearance of the comet was not unlike that of the Nebula in Andromeda, except that it was almost circular instead of elliptical in shape. The colour of the comet was whitish, and the nucleus was rather ill-defined. The spectrum was to a large extent continuous, but there were also unmistakable bright flutings. These were brightest in the nucleus, but they also extended faintly throughout the whole mass. Direct comparisons with the blue base of a spirit-lamp flame showed coincidences with all the flutings, except the bright one in the violet which is characteristic of hydrocarbons. The fluting near *b* was by far the brightest, and next in order of intensities came those near λ 474 and 564. The continuous spectrum extended from about D to a little beyond λ 474. On the 22nd the nucleus was much less central than on the previous evening, probably owing to further development of a short bushy tail. The spectrum, however, showed no obvious differences, except that the brightest fluting had slightly increased in intensity. On the 23rd the form and spectrum were practically the same as on the 22nd. The observations were made with a 10-inch refractor, but the comet was easily seen in the 3-inch finder.

The comet had obviously got beyond the earlier temperature stages before I observed it, and it will be highly interesting to notice if the further changes indicated by Prof. Lockyer's discussion of cometary spectra (see p. 20) take place. These will be most obvious in the faintest band (λ 564) owing to the superposition of the bright flutings of manganese and lead. Changes of the form or wave-length of this band should therefore be particularly noted in further observations. It is, of course, desirable that the observations should be made independently by more than one observer. In my observations of May 21 I was very much struck by the resemblance of the comet to the Nebula in Andromeda, both in form and colour, and in spectrum.

On the 27th I again observed the comet, but saw no decided differences, either in its appearance or spectrum.

A. Fowler.

New Variable Star in Cygnus.—Prof. Pickering, of Harvard College, notes in *Astronomische Nachrichten*, No. 2968, that a study of the spectra of the fainter stars is now in progress with the 8-inch Draper telescope. An examination by Mrs. Fleming of photographs taken with small dispersion led to the discovery that the star D.M. + 48°·2940 whose approximate place for 1900 is in R.A. 19h. 40m. 8s., Decl. + 48° 32′ gave a spectrum resembling that of Mira Ceti and other variables of long period. A photographic chart was made, and on comparison with the photographs previously taken of this region proved conclusively that the star is a variable. The photographs compared are of three kinds: (1) trails in which the telescope was at rest and the brighter stars formed lines by their diurnal motion; (2) charts in which the stars formed circular images; (3) spectra formed by placing a prism in front of the object-glass. From the various photographs of the spectrum of this star, it appears that on September 23, 1887, the hydrogen lines *h* and G are shown bright; the star was then estimated as of the 8th magnitude. On June 16, 1888, magnitude being estimated as 9, the spectrum was faintly visible and apparently continuous, but no bright lines were seen. On September 7 of the same year, G was well seen, and *h* was barely visible, the magnitude being again estimated as 8. There is no doubt, therefore, that this is another example of that group of variable stars that exhibit bright hydrogen lines in their spectra when at a maximum.

Paris Observatory.—Admiral Mouchez, the Director of this Observatory, has issued his Report for the year 1889. An account of the resolutions adopted last September by the International Committee for the execution of the map of the heavens is given. It is also noted that the building is completed which is to receive in two or three months the *coudé* equatorial, 0·60 metre aperture and 18 metres focus. M. Lœwy has supervised the details of the installation of this instrument, which will replace, with some advantage to Paris Observatory, the instrument 0·74 metre aperture first intended for it. This latter telescope is attached to Meudon Observatory, and will find there atmospheric conditions more favourable for the use of its great optical power than at Paris.

The electric light has been installed for the lighting of the two *coudé* equatorials and the meridian circle.

For some years, almost the whole force of the Observatory has been engaged in re-observing on the meridian the stars in Lalande's catalogue. This work was commenced about twenty-five years ago, and on account of it other branches of astronomy have had to be neglected. It is, however, nearly completed, and Admiral Mouchez proposes to the Council that a regular spectroscopic service should be instituted. Up to now, spectroscopy has only existed nominally at Paris Observatory, and in appealing to the administration for the necessary funds to organize this new department it is very truly observed that no Observatory can well dispense with spectroscopic accessories, since it is the study of this branch of astronomy that enables the physical constitution of the heavenly bodies to be determined. M. Deslandres, already known for his spectroscopic works, will take charge of this new department.

A Commission has been appointed to investigate the inconveniences that would arise from the laying of the proposed railway line at a distance of about 150 metres from the Observatory. The Report of the Commission, when ready, will have some interest at other Observatories that have been similarly threatened.

MM. P. and P. Henry have continued the photographic work: 38 photographs of stars have been obtained, and 5 plates for the determination of the parallax of Victoria. The constant of photographic refraction has been determined, and lunar photographs having a diameter of 40 cm. have been obtained by direct enlargement.

Many observations have been made of comets. M. Bigourdan has made 300 complete measures of nebulæ; the major planets and the asteroids have received as much attention as the continued bad weather permitted; and, leaving out of consideration the absence of spectroscopic work, which another year may see remedied, the Report is altogether a satisfactory one.

On the Parallax of Double Stars.—At the March meeting of the Royal Astronomical Society, Mr. Arthur A. Rambant directed the attention of astronomers to a paper in which he pointed out the relation connecting the parallax and the relative velocity of the components of a double star with the period and angular elements of its orbit, and discussed the possibility of determining the distance by means of spectroscopic observations of this velocity. The photographs of stellar spectra recently obtained by Prof. Pickering in America and Prof. Vogel at Potsdam are in point of accuracy so far in advance of direct eye observations of motion in line of sight that they seem to demonstrate the possibility of applying the method described to the determination of parallax, and the author shows how the

parallax (π) of a star can be immediately deduced if its velocity (V) in miles per second in the line of sight has been determined by observation. The advantages to be expected from spectrographic observations of double stars for which πV is greater than 0·1 are shown to be

(1) An independent check on the parallax where this has been determined trigonometrically.

(2) A determination of the parallax where, owing to its smallness, the trigonometrical method fails.

(3) A determination of the sign of the inclination which will remove the ambiguity attaching to the situation of the orbit.

It is to be hoped that astronomers who have the requisite instruments for this kind of observation may be induced to take up what appears to be a promising field of work.

TURIN OBSERVATORY.—We have received various publications from the Observatory of the Royal University of Turin. Amongst them we find convenient ephemerides of the sun and moon for 1889 and for 1890 calculated for the horizon of Torino by Señors Porro and Aschieri respectively, and a note by the former observer on the total eclipse of the moon on January 28, 1888. The difference of longitude between the meridian circle at Turin Observatory and Milan Observatory has also been redetermined. The value found in 1823 was 5m. 58·85s., and the value now found is 5m. 58·736 ± 0·006; thus the difference between the two observations is only 0·11s., although the former was not made by telegraphy.

A CONTRIBUTION TO THE ETIOLOGY OF DIPHTHERIA.[1]

THE microbe, which was first described by Klebs (at the Wiesbaden Congress in 1883), then isolated and grown in artificial cultures by Löffler (*Mitth. aus dem K. Gesundheitsamte*, vol. ii.) from human diphtheritic membrane, was shown by this observer to act virulently on various animals. The Klebs-Löffler bacillus—by which name the diphtheria microbe is known—is the one with which also Roux and Yersin (*Annales de l'Institut Pasteur*, ii., 1888, No. 12) obtained positive results on guinea-pigs.

In the Reports of the Medical Officer of the Local Government Board for 1888-89 and 1889-90, I have shown that there occur in diphtheritic membranes two species of bacilli, very similar in morphological respects, and also in cultures on serum and on agar, but differing from one another in this, that one species, Klebs-Löffler bacillus No. 1, is not constant in diphtheritic membranes, does not grow on solid gelatine at 19°–20° C., and does not act pathogenically on animals; the other species, Klebs-Löffler bacillus No. 2, is constant in diphtheritic membranes, in fact is present even in the deeper layers of the membranes in great masses and almost in pure culture, acts very virulently on animals, and grows well on gelatine at 19°–20° C. Löffler, and after him other observers (Flügge, "Die Mikroorganismen," 1886), considered it as a character of the diphtheria bacillus that it does not grow on gelatine below 22° C., but this character, though true of the Klebs-Löffler species No. 1, does not appertain to the diphtheria bacillus species No. 2. In fact, there is no difficulty in obtaining pure cultures of this bacillus on gelatine if a particle of diphtheritic membrane be taken and well shaken in two or three successive lots of sterile salt solution, and from the last lot plate cultivations on gelatine are made. In this way I have obtained the diphtheria bacillus in great numbers of colonies and in pure culture. Zarniko (*Centralbl. f. Bakteriol. u. Parasit.*, vol. vi., 1889, p. 154) and Escherich (*ibid.*, vol. vii., 1890, p. 8) both state that the diphtheria bacillus does grow on gelatine below 20° C.

This bacillus diphtheriæ acts very virulently on guinea-pigs on subcutaneous inoculation; at the seat of the injection a tumour is produced, which in its pathology and in microscopic sections completely resembles the diphtheritic tissue of the human. In human diphtheria the diphtheria bacillus is present only in the diphtheritic membrane, but neither in the blood nor in the diseased viscera; the same holds good for the experimental guinea-pigs. In subcutaneous inoculation with artificial culture, though it causes in these animals acute disease and death—the lungs, intestine, and kidney are greatly congested—the diphtheria bacillus remains limited to the seat of inoculation. It was for these reasons that Löffler concluded that in diphtheria the diphtheritic membrane alone is the seat of the multiplication of the diphtheria bacillus, and that here a chemical poison is produced, which absorbed into the system causes the general diseased condition and eventually death. Roux and Yersin have then separated from artificial broth cultures the bacilli and the chemical products, and, by the injection of these latter alone into guinea-pigs, have produced a general effect. I have in this year's Report to the Medical Officer of the Local Government Board (1889-90) shown that in these experiments of injection of cultures into guinea-pigs, an active multiplication of the diphtheria bacilli at the seat of inoculation can be demonstrated by culture experiments; from the local diphtheritic tumour and the nearest lymph glands the diphtheria bacilli can be obtained in pure culture on gelatine.

On various occasions during the last three years information has reached me by Health Officers (Dr. Downes, Mr. Shirley Murphy, Dr. Thursfield) as to a curious relation existing between a mysterious cat disease and human diphtheria in this manner, that a cat or cats were taken ill with a pulmonary disease, and while ill were nursed by children, and then these latter sickened with well-marked diphtheria. Or children were taken ill with diphtheria, and either at the same time or afterwards the cat or cats sickened. The disease in the cat was described as an acute lung trouble; the animals were quiet, did not feed, and seemed not to be able to swallow; in some cases they recovered, in others they became emaciated, while the lung trouble increased, and ultimately they died. In one instance—in the north of London, in the spring, 1889—this cat malady, occurring in a house where diphtheria soon afterwards appeared amongst the children, was of a widespread nature; a veterinary surgeon—Mr. Daniel—informed me that at that time he had several patients amongst cats affected with the disease, consisting in an acute catarrhal affection, chiefly of the respiratory passages. He furnished me with two such animals: one that after an illness of several weeks had died, another that was sent to me in a highly emaciated state, affected with severe broncho-pneumonia; this animal was paralyzed on the hind limbs. In both instances the *post-mortem* examination showed severe lung disease, broncho-pneumonia, and large white kidneys due to fatty degeneration of the entire cortex. A similar condition is met with in the human subject in diphtheria. Further, I received from Dr. Thursfield, of Shrewsbury, the body of a cat that had died after a few days' illness from pneumonia in a house in which children were ill with diphtheria; another cat in the same house that became next ill with the same lung trouble also succumbed. The *post-mortem* examination of the animal that I received showed severe broncho-pneumonia and large white kidneys, the entire cortex being in a state of fatty degeneration.

Subcutaneous inoculations of cats were carried out with particles of fresh human diphtheritic membranes and with cultures of the diphtheria bacillus (Report of the Medical Officer of the Local Government Board, 1889-90); hereby a local diphtheritic tumour was produced at the seat of inoculation, and a general visceral disease; in the cases in which death followed after a few days the lungs were found much congested; when death followed after one or more weeks, the lungs showed broncho-pneumonia and the kidneys were enlarged and white, the cortex being in a state of fatty degeneration; if the disease in the animals lasted beyond five to seven days, both kidneys were found uniformly white in the cortex; if of shorter duration, the fatty degeneration was sometimes only in patches. Although in these experiments the bacillus diphtheriæ was recoverable by cultivation from the diphtheritic tumour at the seat of inoculation, there were no bacilli found in the lungs, heart's blood, or kidney, and the conclusion is justified that, just as in the human diphtheria and in the diphtheria produced by subcutaneous inoculation in the guinea-pig, so also in these experimental cats the visceral disease must be a result of the action of a chemical poison produced by the diphtheria bacillus at the seat of inoculation.

From this it is seen that the similarity between the artificial disease and the natural disease in the cat is very great, and the question that presents itself is, In what manner does the animal receive or give the diphtheritic contagium in the natural disease? The natural disease in the cat is in its symptoms and pathology a lung disease, and it is reasonable to suppose from analogy that the lung is the organ in which the diphtheritic process in the cat has its seat. The microscopic examination of the diseased lung

[1] Paper read before the Royal Society by Dr. E. Klein, F.R.S., on May 22. This research was undertaken for the Medical Department of the Local Government Board, and was communicated to the Royal Society with the permission of the Medical Officer.

of cats that died from the natural disease bears this out, the membrane lining the bronchi in the diseased portions of the lobules presenting appearances which in microscopic character coincide with the appearances in the mucous membrane of the human fauces, pharynx, or larynx in diphtheria. But the correctness of the above supposition, that diphtheria has its seat in the lung of the cat naturally diseased, was proved by direct experiment. Broth culture of the bacillus diphtheriæ was introduced into the cavity of the normal trachea without injuring the mucous membrane. The animals became ill with acute pneumonia, and on *post-mortem*, two to seven days after, there was found extensive pneumonia, and fatty degeneration of the kidney. The bronchi, infundibula, and air-cells of the inflamed lobules were found occluded by, and filled with, exudation, which under the microscope bears a striking resemblance to human diphtheritic membranes, and in the muco-purulent exudation in the large bronchi and trachea the diphtheria bacilli were present in large numbers.

During the last ten or twelve years certain epidemics of diphtheria have occurred which were traced to milk, but the manner in which that milk had become contaminated with the diphtheritic virus could not be demonstrated, although the evidence as to the milk not having been directly polluted from a human diphtheria case was very strong. The epidemic of diphtheria that prevailed in the north of London in 1878, investigated by Mr. Power for the Local Government Board, then the epidemic that occurred in October 1886 at York Town and Camberley, the epidemic in Enfield at the beginning of 1888, and in Barking towards the autumn of 1888, were epidemics of this character. Mr. Power, in his Report to the Local Government Board on the York Town and Camberley outbreak, states (p. 13) that a veterinary surgeon had certified that the cows from whom the infected milk was derived were all in good health, but that two of the cows showed "chaps" on their teats, and he adds that even two or three weeks after the epidemic had come to an end —the use of milk having been in the meanwhile discontinued— he saw at the farm one cow which had suffered chapped teats. At Enfield a veterinary inspector had also certified that the cows were in good health; but at Barking the veterinary inspector found sores and crusts on the udder and teats of the cows.

I have made experiments at the Brown Institution on milch cows with the diphtheria bacillus, which appear to me to throw a good deal of light on the above outbreaks of diphtheria.

Two milch cows[1] were inoculated with a broth culture of the diphtheria bacillus derived from human diphtheria. In each case a Pravaz syringeful was injected into the subcutaneous and muscular tissue of the left shoulder. On the second and third days there was already noticed a soft but tender swelling in the muscle and the subcutaneous tissue of the left shoulder; this swelling increased from day to day, and reached its maximum about the end of the week; then it gradually became smaller but firm. The temperature of both animals was raised on the second and third day, on which days they left off feeding, but after this became apparently normal. Both animals exhibited a slight cough, beginning with the eighth to tenth day, and this gradually increased. One animal left off feeding and ruminating on the twelfth day, "fell in" considerably, and died in the night from the fourteenth to fifteenth day; the other animal on the twenty-third to twenty-fourth day left off taking food, "fell in" very much, and was very ill: it was killed on the twenty-fifth day.

In both animals, beginning with the fifth day, there appeared on the skin of the udder, less on the teats, red raised papules, which in a day changed into vesicles, surrounded by a rim of injected skin; the contents of the vesicles was a clear lymph, the skin underneath was much indurated and felt like a nodule; next day the contents of the vesicle had become purulent, *i.e.* the vesicle had changed into a pustule; in another day the pustule dried into a brownish-black crust, with a sore underneath; this crust became thicker and larger for a couple of days, then became loose, and soon fell off, a dry healing sore remaining underneath. The whole period of the eruption of papules, leading to vesicles, then to pustules, and then to black crusts, which, when falling off, left a dry healing sore behind, occupied from five to seven days. The eruption did not appear in one crop: new papules and vesicles came up on the udder of one cow almost daily between the fifth and eleventh day after inoculation, in the other cow between the sixth and tenth day; the total number of vesicles in the fomer cow amounted to about twenty-four on the udder, four on the teats; in the latter they were all on the udder, and amounted to eight in all. The size of the vesicles and pustules differed: some were not more than $\frac{1}{8}$th of an inch, others larger, up to $\frac{1}{2}$-$\frac{3}{4}$ of an inch in diameter; they had all a rounded outline, some showed a dark centre. From one of the above cows on the fifth day milk was received from a healthy teat, having previously thoroughly disinfected the outside of the teat and the milker's hand; from this milk cultivations were made, and it was found that thirty-two colonies of the diphtheria bacillus without any contamination were obtained from one cubic centimetre of the milk.

Unlike in the human, in the guinea-pig and in the cat the diphtheria bacillus passed from the seat of inoculation into the system of the cow; this was proved by the demonstration of the diphtheria bacillus in the milk. But also in the eruption on the udder, the presence of the diphtheria bacillus was demonstrated by microscopic specimens and particularly by experiment. With matter taken from the eruption—vesicles and pustules—of the udder, two calves were inoculated into the skin of the groin; here the same eruption made its appearance: red papules, rapidly becoming vesicular, then pustular, and then became covered with brown-black crusts, which two or three days after became loose and left a dry healing sore behind. More than that, the calves that showed this eruption after inoculation became affected with severe broncho-pneumonia and with fatty degeneration of the cortex of the kidney. In the two cows above mentioned, on *post-mortem* examination, both lungs were found highly congested, œdematous, some lobules almost solid with broncho-pneumonia in the upper lobes and the upper portion of the middle or lower lobe respectively; the pleural lymphatics were filled with serum and blood. Hæmorrhages in the pericardium and lymph glands, and necrotic patches were present in the liver. At the seat of inoculation there was in both cases a firm tumour consisting in necrotic diphtheritic change of the muscular and subcutaneous tissue. In this diphtheritic tumour continuous masses of the diphtheria bacillus were present; their gradual growth into and destruction of the muscular fibres could be traced very clearly.

It appears then from these observations that a definite disease can be produced in the cow by the diphtheria bacillus, consisting of a diphtheritic tumour at the seat of inoculation with copious multiplication of the diphtheria bacillus, a severe pneumonia, and necrotic change in the liver; the contagious nature of the vesicular eruption on the udder and excretion of the diphtheria bacillus in the milk prove that in the cow the bacillus is absorbed as such into the system.

From the diphtheritic tumour, by cultivation, pure cultures of the diphtheria bacillus were obtained; a small part removed from the tumour with the point of a platinum wire, and rubbed over the surface of nutrient gelatine or nutrient agar, yielded innumerable colonies of the diphtheria bacillus without any contamination. In cultural characters in plate, streak, and stab cultures and in cover-glass specimens of such cultures, this cow diphtheria bacillus coincided completely with the human diphtheria bacillus, but in sections through the diphtheritic tumour of the cow a remarkable difference was noticed between it and the bacillus from the cultures; inasmuch as in the tissue of the tumour the masses of the microbe, both in the necrotic parts, as also where growing into and destroying the muscular fibres, were made up of filaments, granular threads, some of which possessed terminal oval or flask-shaped swellings. But that it was really the diphtheria bacillus was proved by culture experiments and by cover-glass specimens. In the latter, the transitional forms between typical diphtheria bacillus and long filaments with terminal knob-like swellings, with spherical or oblong granules interspersed here and there in the threads, could be easily ascertained. In the large number of cultivations that were made of the fresh tumour in both cows, the colonies obtained were all of one and the same kind, viz. those of the diphtheria bacillus; no contamination was present in any of the cultivations.

Appendix, *May* 20.—At the beginning of the month of April two cats died at the Brown Institution, after having been ill for several days, with symptoms like those of natural cat diphtheria. Between the beginning of April and the beginning of May, 14 cats became similarly affected, some more severely than others, and some died with the characteristic morbid change This epidemic, as it may be called, commenced with the illness of the

[1] The cows had been kept under observation previous to the experiment for ten days, and were in all respects perfectly normal.

first two cats about the end of March; and the question arises as to how the disease originated in these two animals. No cats had been ill in their shed, and the two affected ones were healthy when received at the institution some weeks before. But during the latter half of March there were in the stables of the institution two milch cows ill with diphtheria induced by inoculation with the human diphtheria bacillus—in fact, the two cows already referred to. The diphtheria bacillus was found in the milk drawn from one of these animals on the fifth day after inoculation, and orders were given to the attendant that the milk of both cows was to be thrown away. This order was not obeyed, for part of the milk was given to the two cats above mentioned, and they sickened as described within a day or two afterwards. It ought to be mentioned that the man in attendance on the cows had also charge of the cats, but, in view of the fact that he was himself free from the disease, the possibility of his having conveyed it from the cows to the cats may be disregarded.

SOME NOTES FROM SOUTH AMERICA.

IN the course of a visit to the plains of South America, not far from Rosario de Santa Fe, in the Argentine Republic, lasting from September 1888 until March 1889, I was able to make some miscellaneous notes of more or less interest. From these I select the following:—

(1) *The Rhea, or South American Ostrich.*—The cock bird makes the nest, hatches the eggs, and takes care of the young birds. We had some (so-called) "tame" ostriches about the *estancia.* One day I came across the old cock in a nest that it had made in the dry weeds and grass. Its wings and feathers were loosely arranged, and looked not unlike a heap of dried grass; at any rate the bird did not attract my attention until I was close on him. The long neck was stretched out close along the ground; the crest-feathers were flattened; and an appalling hiss greeted my approach. It was a pardonable mistake if for a moment I thought I had come across a huge snake, and sprang back hastily under this impression. This *might* be cited as an instance of (unconscious) "protective mimicry."

When a troop of these birds is alarmed while yet at a distance from the enemy, they run with their wings either close to the side in the normal position, or raised above the back into a narrow wedge that offers but little resistance to the air. But when a bird is somewhat pressed, it usually droops the wings loosely, almost trailing them. And when in danger of being caught by dogs, or struck by the *bolas* of a horseman, it begins to dodge and twist in a very curious manner, the wings assuming various positions. It would seem as though the wings, thus used, may help the bird to make its sudden halts and turns; and also, when dogs are used in the chase, to baffle the attacks of these enemies. It was very curious to see the "tame" ostriches indulging in these freaks even when unpursued by the dogs of the *estancia.* The birds would rush straight along, turn and twist, contort their necks into very comical shapes, jump, and not unfrequently tumble over in their efforts to perform some unusually complicated evolution.

I may add that in the course of some years of "ostrich-running," my brother once observed a troop of these birds swim a river that crossed their path. He himself followed, and found that the river was really out of their depth; they were not wading.

(2) *Snakes: the "Vivora de la Cruz."*—On October 6, 1888, we came across one of these common poisonous snakes, probably not long roused from its winter torpor. The dogs stood round it barking; and it remained, threatening a strike. With its tail (and against the grass?) it made a very distinct though not a loud burring, vibrating sound. This, my brother told me, was usual. Yet there is no kind of "rattle" on the tail.

At the end of March 1889, after I had returned to England, my brother killed a large *vivora de la cruz;* and, observing that it appeared to be very thick in the body, he cut it open in order to examine it. Inside was a string of transparent bags, six or seven in number, connected with one another. In each of these could be seen a fully-formed young snake, about 6 inches long, as far as he could say without exact measurement, coiled up. Two of the bags he cut open; and the young snakes, released, both threatened to strike anything that approached them, and made, though of course on a very small scale, the vibrating, burring noise with the tail.

(3) *The Intelligence (?) of Ants.*—One kind of small ant, if not more, makes large nests underground, in the shorter grass. A network of paths, clear of grass, about 2 inches wide near the nest, converge towards this latter; being the roads by which the ants bring home forage. These paths are of all lengths from 10 yards up to 100 yards; and, as one traces them further from the nest, they break up into smaller branches and are finally lost. As a general rule, one may say that streams of ants carrying leaves, buds, flowers, seeds, and other valuable odds and ends are always moving towards the nest, while empty-mouthed ants are meeting and passing them on their outward journey to the foraging grounds. Having, however, noticed a few burdened ants proceeding with great difficulty against the general stream of their burdened fellow-citizens, I tried the experiment of turning some of these carriers round when they had nearly reached home. The general conclusion I came to was that these ants did not then understand in what direction the nest lay, nor did they (as far as I could see) draw any conclusions from the fact that they now *met* the stream of carriers with which they had previously been travelling.

Thus, one ant, carrying a (relatively) huge burden, I reversed in direction when already near the nest. I then followed it for about 8 yards (or about 20 minutes of time as far as I can say) in its mistaken reversed course away from the nest. Though it met and collided with quantities of burdened ants, and was passed in the same direction as its own by unburdened ants only, it did not seem to take the hint. Its final return home was the result of accident, as far as I could tell; it having got up "the right way round" after a severe fall.

Still it must be noticed that among the undisturbed ants very few went the wrong way.

I dug a hole in one of the paths, on several occasions. The hole was small; and it was easy, though not so convenient, to go round by the side over the very short grass. Nevertheless it required the falling of very many ants into the hole, and the leaving of quite a pile of leaves there, before the stream learned to pass about about one inch to one or other side, and so to avoid the pitfall. Some ants even turned back; and I left them carrying their burdens back to the foraging grounds again.

(4) *Grasses.*—I noticed two grasses concerning whose seeds a remark or two may be of interest.

(*α*) One is called "*Flechilla.*" Its seed bears a very sharp point; and a number of hairs, turned back from the point, prevent the return of the seed from any body into which it has penetrated. Attached to the seed is always a piece of stem curiously twisted like rope. The whole answers somewhat to an arrow-head with barbed point and with shaft attached. My brother, whose observations extend over more than twenty years, tells me that this seed penetrates into the bodies of sheep, and is found in their internal organs. The spring lambs, which are left unshorn until summer is over, are especially troubled with the flechilla. When one of these animals dies and is skinned, it is very commonly found that quantities of these seeds have penetrated the skin, the heads being found in the flesh underneath; and my brother has found them in the liver. It is believed that this is the cause of some deaths among the animals.

(*β*) Another remarkable grass is the "*Paja voladora.*" This grows in tufts, not unlike those of a small "Pampas grass." From slender stems there stand out still slighter branches, at the end of which are the seeds; the whole, stem and seeds, having somewhat the appearance of a miniature fir-tree as regards shape, and having various lengths up to 2 feet or so. When ripe, these stems with the seeds blow bodily away in the first strong wind. I have seen them flying through the air, looking from afar rather like a dust-cloud against the sky; and half rolling, half drifting, over the living grass of the plain, before the sudden onset of a *tormenta* (storm with wind). This drifting movement over the grass had a curiously bewildering effect on the eye. When the storm is over, the grass is found in drifts against the posts and wires of the fences; these collections remind one strongly of snow-drifts.

On December 16 (or so), 1888, a terrible accident occurred on the railway between Candalaria and Guardia de la Esquina. A cutting had become filled with this *Paja voladora;* and the engine set fire to it as it passed. However, thanks mainly to a suitable wind, the train got safely through. But in the afternoon of the same day the train re-passed in the opposite direction, and the cutting had in the meantime become filled again with

these seed-stems. The wind was, in this return journey, in such a direction as to favour the tendency of the burning grass to set fire to the carriages. They caught fire. About eight persons were totally consumed, hardly even bones being found to tell the tale; and eighteen escaped up the banks in a pitiable condition. I do not know how many of these are now alive.

W. LARDEN.

ON THE PROPERTIES OF LIQUEFIED GASES

M. E. MATHIAS has just published in the form of an inaugural thesis (Gauthier-Villars, Paris), an important investigation on the latent heat of vaporization of liquefied gases. The value of this coefficient for sulphurous acid, carbonic acid, and nitrous oxide was determined experimentally throughout a considerable range of temperature by the following method. The gases were first liquefied in a small copper cylinder, 9 cm. in height, 3 cm. in diameter, with walls 0·38 cm. in thickness. The cylinder was then weighed and introduced into an ordinary Berthelot calorimeter, and the liquefied gas was allowed to evaporate slowly, the pressure being constantly read off on a Bourdon gauge and regulated by means of two conical screw taps. The calorimetrical method employed was a null one (devised by the author), the heat absorbed by the evaporation of the liquid being compensated for by adding sulphuric acid of known strength to the water in the calorimeter, at such a rate as to keep its temperature approximately constant. The total amount of heat absorbed was thus easily determined, while the correction for cooling was reduced to a minimum. When necessary the laboratory was heated by means of regulated gas-burners, so that the liquid in the calorimeter and the surrounding atmosphere were at the same temperature in all cases. Seven experiments on liquid sulphurous acid between the temperatures of $+5°·74$ and $+19°·95$ gave values for L, the latent heat of vaporization, which may be expressed by the empirical formula—

$$L = (91·87 - 0·384t - 0·000340t^2) \text{ Cal.}$$

Nineteen experiments on liquid carbonic acid between $+6°·65$ and $+30°·82$ may be expressed by the formula—

$$L^2 = [117·303 (31 - t) - 0·466 (31 - t^2)] \text{ Cal.}$$

The numbers obtained afford a satisfactory verification of Clapeyron's formula, as calculated from constants previously determined.

Owing to the great difficulty of obtaining nitrous oxide free from nitrogen, the results obtained with this gas can only be regarded as qualitatively correct. But the graphic representation of fifteen experiments, performed between the temperatures of $+5°·37$ and $+34°$, show that the curve representing the variation of the latent heat with the temperature is exactly of the same form for nitrous oxide as for carbonic acid. In both cases the tangent to the curve at the critical point is rigorously perpendicular to the temperature axis. We may from this conclude that at the critical point L is rigorously equal to zero, and hence from Clapeyron's formula that the specific volume of the liquefied gas and its saturated vapour are rigorously equal, a fact questioned lately by Cailletet and Colardeau. It follows, moreover, from the thermodynamical equation—[1]

$$m' = m + dL/dt - L/T,$$

where m' is the "specific heat of the saturated vapour"—that at the critical point,

$$m' = -\infty.$$

Now at the temperatures at which experiments have been made on ordinary liquids (water, ether, acetone, &c.), m', though negative, was found to increase with rise of temperature; but since we may conclude from these experiments that near the critical point it will decrease, it follows that it must at some intermediate temperature pass through a maximum. It follows also that if m', while increasing, pass through a zero value, that it will pass through a second zero value in the opposite sense. As m' for carbonic acid and nitrous oxide is negative and decreasing between $-50°$ and $+30°$, if a zero value exist for these gases, it must be at a very low temperature. In the case of sulphurous acid, the results obtained were shown to confirm certain formulæ given by Bertrand in his "Thermodynamique," and applicable to saturated vapours at temperatures much below the critical point. The memoir as a whole is masterly.

[1] See Verdet, "Théorie Mécanique de la Chaleur," i. p. 258.

NOTES ON INDIAN INSECT PESTS.

THE Government of India has evidently begun to realize the importance of the study of injurious insects, and the methods of combating them. Some time ago, Mr. E. C. Cotes, of the Indian Museum, published the first two numbers of "Notes on Economic Entomology," dealing respectively with the wheat and rice weevil in India, and with insecticides and the methods of applying them. This series has been discontinued, and its place has been taken by "Notes on Indian Insect Pests."

The first number of the new series contains notes on the Rhynchota, by Mr. Atkinson, the most detailed of which deals with the rice sapper (*Leptocorisa acuta*). These insects settle on the rice ear, sometimes to the number of ten on one ear, and, extracting the milky juice of the grain, leave the husk dry. Unfortunately, nothing is known of the life-history of this pest. Mr. Atkinson also describes a new genus and species of Coccidæ (*Pseudopulvinaria sikkimensis*), found on the under surface of the leaves of oaks, chestnuts, and cinchona: hitherto this has not appeared in sufficient numbers to effect much damage.

Mr. De Nicéville contributes an account of two injurious butterflies: one, which he identifies as *Suastus gremius*, devours the young and tender rice-shoots in the paddy-fields, but fortunately avoids the more mature plants. As a preventive for this pest, Mr. De Nicéville recommends raising the earthen walls round each plantation, so as to completely submerge the rice; this would prove fatal to all stages in the life-history of the butterfly, with the doubtful exception of the egg. The other report deals with *Lampides elpis*, whose larva devours the buds and young fruit of the Cardamom. Many allied forms have a gland on the eleventh segment, secreting a sweet fluid, much sought after by ants, but this seems to be absent in the species here described.

The remainder of the number is made up of thirteen reports and numerous short notes contributed by Mr. Cotes. Two of these reports are extensions of his "Notes on Economic Entomology," mentioned above. No mention is made of the Strawsonizer, whose value as a disseminator of insecticides has recently been recognized in England. The remaining eleven deal with caterpillars which attack the tea plant, sâl trees, rice, *Cedrela toona*, sugar-cane, sorghum, and the blankets belonging to the Army Clothing Department, and with various species of beetle injurious to the rice, bamboo, mango, and shorea tree. The beetle, which lives under the bark of the last-mentioned tree, closely resembles the *Tomicus chalcographus*, which is so injurious to the spruce in Europe.

The notes which conclude the work are often very fragmentary, but are full of suggestion, and there is no room to doubt that the lacunæ in the life-history of the insects with which they deal will soon be filled up, now that the authorities of the Indian Museum have provided a journal which will prove a means of intercommunication between the numerous entomologists and cultivators scattered over India.

The number is illustrated by four good plates of photo-etchings executed in Calcutta.

A. E. S.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—An elector (who must be a Head of a College) to the Sadlerian Professorship of Mathematics will be elected by the resident members of the Senate on June 3, from 1 to 2 p.m. The vacancy is caused by the death of Dr. Phelps, Master of Sidney Sussex College.

A. R. Forsyth, F.R.S., the author of the well-known "Treatise on Differential Equations," has been approved for the degree of Doctor in Science.

Dr. Hill, Master of Downing College, announces a class in Practical Histology, to be held during the Long Vacation.

The General Board of Studies recommend that the stipends of the following teachers of science be increased:—Mr. Gadow, King's College, Lecturer in Advanced Morphology, from £100 to £150; Mr. Marr, St. John's College, Lecturer in Geology, from £100 to £150; Mr. Harker, St. John's College, Demonstrator in Geology and Lecturer in Petrology, from £100 to £150; Mr. Barber, Christ's College, Demonstrator in Botany, from £100 to £150; an additional Demonstrator in Chemistry at a stipend of £100.

A conference on the local lectures under the University

Extension Scheme is to be held in Cambridge on July 9 and 10. Courses of lectures and practical work are to be arranged for students for local centres who are to reside in Cambridge during the month of August.

A very interesting report on the progress of the Extension movement by Dr. R. D. Roberts appears in the *Cambridge University Reporter* of May 27. The account he gives of the enthusiasm and energy displayed by certain of the Students' Associations attending Extension lectures is most encouraging, and shows how wide-spread is the influence for good exerted by the University in this connection.

SCIENTIFIC SERIALS.

THE *Quarterly Journal of Microscopical Science* for April 1890 contains papers on *Phymosoma varians*, Selenka, by Arthur E. Shipley (plates i. to iv.). The material for this paper was collected by Mr. Weldon in the Bahama Islands, where the species was fairly abundant in the soft coral rock. The general morphology and minute structure of this animal are described in great detail, and accompanied by some excellent illustrations; the head of Phymosoma is surrounded by a stiffened vascular horseshoe-shaped lip, the dorsal ends of which are continuous with the ends of a hippocrepian lophophor, which bears a crown of about eighteen tentacles—the number being always even; between this lophophor and the vascular lip is the crescentiform opening of the mouth. The author would keep the genus Phoronis as a form closely allied to the more normal *Gephyrea inermia*, and compares the head of Phymosoma as seen from above with a view of Phoronis.—On the spinning apparatus of the geometric spiders, by C. Warburton (plate v.). Proves by a series of interesting experiments that a spider's line does not consist of many strands fused or woven together, but ordinarily of two or four distinct threads; the ground line of the spiral is double only, and the two strands are bound together merely by the viscid matter, which envelops them.—On the structure and functions of the cerata or dorsal papillæ in some Nudibranchiate Mollusca, by Prof. W. A. Herdman (plates vi. to x.). In some six genera of British Nudibranchs examined, Herdman found that the dorsal papillæ, "cerata" of Lankester, were of two kinds—(1) those containing diverticula of the liver, as in the cases of Eolis and Doto, (2) those which were essentially but processes of the body-wall having no connection with the liver, as in Tritonia, Ancula, and Dendronotus. In Doris there are true branchiæ and no cerata. In Ancula both branchiæ and cerata are present. In Tritonia and Dendronotus there are cerata but no true branchiæ. In Doto and Eolis there are no true branchiæ. Morphologically all the forms of cerata are probably epipodial processes; they are not of primary importance either in respiration or in digestion, but give to the animals, by their varied shape and colours, appearances which are in some cases protective and mimetic, and in others conspicuous and warning, as may be best suited to the individual surroundings and mode of life.—Further observations on the histology of striped muscle, by C. F. Marshall (plate xi.).—On Chætobranchus, a new genus of Oligochætous Chætopoda, by Dr. A. G. Bourne (plate xii.). This remarkable worm was found in the mud from a "tank" in Madras town; it is furnished with a remarkable series of branchial processes, dorso-laterally placed—a pair to each of the anterior segments, commencing with the second segment; these processes completely surround a portion of the dorsal setæ bundles. The species has been named *Chætobranchus semperi*.—On the presence of Ranvier's constrictions in the spinal cord of Vertebrates, by Dr. W. T. Porter, of St. Louis (plate xii. *bis*).—A note to the editor from Prof. Bütschli, of Heidelberg, giving an account of his experimental imitation of protoplasmic movements. These protoplasma-like streaming properties of minute globules of a specially treated olive oil are of extreme interest.

American Journal of Science, May 1890.—Experiments with a pendulum-electrometer, illustrating measurements of statical electricity in absolute units, by Alfred M. Mayer. The apparatus described affords an inexpensive and ready means of presenting clearly to a class the nature of measurements of statical electricity in absolute units; the instrument may be made to measure to the $\frac{1}{10}$ of a dyne, and a series of experiments are given to show that it gives the law of inverse squares, serves to determine the law of dissipation of an electric charge, and that it allows measures to be made of electrical distribution on conductors and the determination of quantity and potential.—On electric potential as measured by work, by the same author. A graphical illustration is given of the fact that in the case of two electrified spheres the potential function is a measure of work.—An elementary proof of the earth's rigidity, by Geo. F. Becker. It is proved that a simple strain spheroid affords an approximation to the deformation of an elastic globe sufficiently close to serve as a basis for Sir William Thomson's demonstration of the rigidity of the earth; the whole subject also being presented in a clear and elementary manner.—On the hornblende of St. Lawrence County, N.Y., and its gliding planes, by George H. Williams. From the evidence brought forward it is concluded that an alteration of the symbols for the terminal planes of hornblende is necessary to show its analogy to pyroxene; and that this change must be made in accordance with the assumption that the gliding plane, now called the orthodome $P\bar{\infty}$ (101) is the basal pinacoid OP (001) as suggested by Tschermak in 1884.—Note on some secondary minerals of the amphibole and pyroxene groups, by Whitman Cross. In the course of the microscopical examination of some rocks from Custer County, Colorado, the author has observed two peculiar minerals of secondary origin, one an amphibole, and the other a pyroxene, and now describes their unusual properties, relationships, and mode of formation.—On spangolite, a new copper mineral, by S. L. Penfield. The specimen examined consisted of a rounded mass of impure cuprite mostly covered with hexagonal crystals of the new mineral. A full description of the habit, optical and physical properties, and chemical composition of the crystals is given.—Archæan axes of Eastern North America, by James D. Dana. The partly or wholly Archæan ranges in New England and Canada parallel and to the east of the Appalachian *protaxis* are described, and the geological importance of the included troughs or basins pointed out.—On the metamorphic strata of South-Eastern New York by Frederick J. H. Merrill.—The radiant energy of a standard candle; mass of meteors, by C. C. Hutchins. The whole radiant energy of the candle used was found to be 1.23×10^8 ergs per second, and the radiant energy of the visible part 2.46×10^6 ergs per second. The author also points out how such measures may be used to determine the mass of meteors.—Meteoric iron from North Carolina, by L. G. Eakins.—Distinctive characters of the order Hallopoda, by O. C. Marsh.—Additional characters of the Ceratopsidæ, with notice of new Cretaceous Dinosaurs, by the same author.

Botanische Jahrbücher, von A. Engler, vol. xi., contains the following papers:—An essay on the biological relations of the flower of *Aconitum*, by Dr. M. Kronfeld. He states that *Aconitum* is an excellent example of a flower adapted to a certain insect, and that it is dependent upon *Bombus* for its fertilization, a fact which is further borne out by a comparison of the geographical area of the two, that of *Aconitum* being entirely covered by the area of distribution of *Bombus*.—Dr. O. Drude, on the principles of distinction of the formations of vegetation (*Vegetationsformationen*) as illustrated by the flora of Central Europe.—A description, by L. Wittmack, of the plants belonging to the *Bromeliaceæ*, collected by Herr F. C. Lehmann in Guatemala, Costarica, Columbia, and Ecuador.—A description of new species of Nyctaginaceæ, by Dr. A. Heimerl, with one plate.—A monographic sketch of the genus *Helleborus*, by Dr. V. Schiffner.—A contribution to the knowledge of the distribution of the Scotch fir in Northern Germany, in which it is stated that on the mainland it extends north of the Elbe as a native plant, only as far as a line connecting Rostock, Schwaan, Güstrow, Wittenburg, and Geesthacht; in North-West Germany it is native only in the Upper Harz.—An anatomical investigation of the foliage leaves of the Arbutoideæ and Vaccinoideæ in relation to their systematic grouping, and geographical distribution leads Dr. Franz Niedenzu to the following conclusions: that the Arbuteæ are the oldest type, and of them more especially *Arbutus* and *Arctous*, while *Arctostaphylos* is more recent; the most recent group is the *Thibaudieæ*. These results are based upon details of the glandular and other hairs, of the teeth of the leaf, the epidermis and cuticle (130 pp. and 4 plates).—On the influence of the mean direction of the wind on the vegetation in the water, with references also to other phenomena of vegetation which depend upon the direction of the wind in the Western Baltic, by M. J. Klinge.—On a new *Potentilla* from Central America, by Dr. K. Fritsch.—Contributions to the knowledge of the Amaryllidaceæ, by Dr. F. Pax.—A list of the wild plants of the province of Wologda, by N. A. Ivanitzky.—On the

anatomical characters of the Hamamelidaceæ, examined with the object of using them as a basis for the systematic arrangement of the family, by A. Reinsch (1 plate).—A list of the Polypodiaceæ, Gramineæ, Cyperaceæ, and Juncaceæ, collected by Dr. Marloth in South Africa.—On *Cassine domingensis* Spr., by A. Garcke.—A treatise on the genus Platanus, with two plates, by J. Jankó. This paper has special reference to the detail characters of the leaf.—On two *Soldanellas* new to the flora of Hungary, by V. A. Richter.—At the end of the volume are abstracts of many recent memoirs published elsewhere, and a classified list of the most important works on systematic, geographical, and descriptive botany published in the year 1889.

Bulletin de la Société des Naturalistes de Moscou, 1889, No. 2.—On the origin of periodical comets, by Th. Bredichin (in French). The author examines into the cases of division of comets into two or more individuals, endeavouring to classify the better known ones into "families," and gives the formulæ for the cases when the impetus given to the corpuscles of a comet acted under a given angle to the plane of its motion.—Note on the genus *Bombus*, by General Radoszkowski (in French).—The Amphibian fauna of Europe: the *Anura*, by Dr. J. Bedriaga, being a full description (in German) of the two genera *Rana* and *Bufo*, their species, varieties, life, and geographical distribution.

No. 3.—On the modes of propagation of fresh-water fishes, by S. Nikitin (in French). M. Nikitin objects to the too hasty generalizations sometimes arrived at by men of science (especially with regard to Central Asia) as to the former communication between distant fluviatile basins and lakes which now have some species of fishes in common. He points out the possibility of the transport of the eggs of certain fishes by birds, and mentions the fact of young pikes, from six to ten centimetres long, being found in small temporary ponds on the banks of the Moskva river, where they could by no means have migrated themselves. Further inquiry is asked for.—The transport of electrical energy, by J. Weinberg (in German).—On the nesting of *Podoces Panderi*, by N. Zarudny.—The Amphibian fauna of Europe: the *Anura* (continued), by Dr. J. Bedriaga. The genera *Hyla*, *Pelobatus*, *Pelodytes*, *Discoglossus*, *Bombinatur*, and *Alytes*, are considered, and the author describes two new varieties of *Hyla arborea* under the names of var. *orientalis* and var. *Molleri*.—On the influence of weather upon plants and animals, by Alex. Becker (in German).

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 8.—"Experiments on Vapour-Density." By E. P. Perman, B.Sc. Communicated by Prof. Ramsay, F.R.S.

Vapour-density of Bromine.—This work was undertaken in order to see if the results of Prof. J. J. Thomson's experiments could be verified; these appeared to show that bromine vapour dissociated on continued heating at a low pressure, and a comparatively low temperature. The method used was a modification of the Dumas method, by which a series of vapour-density determinations were made at different pressures, with the same identical material. The chief conclusions arrived at are (1) that no dissociation takes place at temperatures as high as 280°, and pressures as low as 20 mm., even on continued heating; (2) that bromine vapour has no tendency to form molecules with more than two atoms, on approaching the liquid state.

Vapour-density of Iodine.—The density of saturated iodine vapour was determined by an adaptation of Kundt's method of determining the velocity of sound in gases. The mean result was 126·9, showing that liquid iodine has the formula I_2.

Induction Spark through Iodine Vapour.—The same apparatus was used as in finding the vapour-density of iodine. No alteration of the wave-length in the iodine vapour (as indicated by the heaps of finely-divided silica on the lower part of the tube) occurred on passing a series of sparks, and then causing the glass piston to vibrate. Sparking does not appear, therefore, to produce permanent dissociation of iodine vapour, notwithstanding the results pointing to a contrary conclusion, obtained by Prof. Thomson. Neither bromine nor iodine vapour, when saturated, threw the silica into heaps; it appears that sound-waves cannot be propagated in a saturated vapour, for condensation will be produced either by the waves of compression or those of expansion (according to the nature of the vapour, and its temperature) and the rates of propagation of the two sets of waves will therefore be different.

Vapour-densities of Sulphuric Anhydride, and Aqueous Hydrochloric Acid.—These were determined by the same method as the vapour-density of bromine. The vapour-density of sulphuric anhydride indicated a formula SO_3, and that of aqueous hydrochloric acid showed that it is a mixture of molecules HCl and H_2O, and not a compound. In all these experiments the quantity of substance in the globe was not found by weighing, but by estimating it volumetrically, portions being drawn off and absorbed in a suitable liquid. The globe was heated by means of a vapour-jacket; the vapours used were those of alcohol, chlorobenzene, bromobenzene, and bromonaphthalene.

The author is greatly indebted to Prof. Ramsay for constant advice and assistance in carrying out the work.

May 22.—"The Chemical Products of the Growth of *Bacillus anthracis* and their Physiological Action." By Sidney Martin, M.D., Pathologist to the Middlesex Hospital. Communicated by Dr. Klein, F.R.S.

The bacilli were grown in a solution of pure alkali-albumin (made from serum-proteids) and of mineral salts of the composition of the salts of the serum.

The cultivation of the bacilli was continued for ten to fifteen days, and the organisms removed by filtering through Chamberlain's filter. The filtrate contained the products of the bacterial growth, viz.:—

(1) *Proto-albumose* and *deutero-albumose*, and a *trace of peptone*: all with the same chemical reactions as the similar bodies formed in peptic digestion.

(2) *An alkaloid.*

(3) Small quantities of *leucin* and *tyrosin*.

The chief characteristic of the anthrax proto- and deutero-albumose is their strong alkalinity in solution—an alkalinity not removed by absolute alcohol, by benzene, chloroform, or ether, or by prolonged dialysis. Acid-alcohol dissolves from the alkaline albumoses a trace of a poisonous body, but this is not in proportion to the toxicity of the albumoses. The albumoses are precipitated in an alkaline condition by saturation with NaCl (proto-albumose) or $(NH_4)_2SO_4$. The alkaloid is soluble in absolute alcohol, amyl alcohol, and in water; insoluble in benzene, chloroform, and ether. It is strongly alkaline in solution, and a powerful base, readily forming salts with acids. The sulphate crystallizes in small needles or prisms; the oxalate in long, branching needles or flat plates. From the salts the alkaloid is easily regained. In solution, the alkaloid is precipitated by phosphotungstic, phosphomolybdic, and phosphoantimonic acids and platinic chloride, but not by potassio-mercuric iodide. It is slightly volatile, and, when kept exposed to the air, it becomes acid, and loses, to a great extent, its poisonous properties.

Physiological Action.

(1) The mixture of anthrax proto- and deutero-albumose is poisonous. In small doses it produces in mice a local subcutaneous œdema, with some sluggishness, ending in recovery. Larger doses produce a greater œdema with more signs of illness, sluggishness leading to prolonged stupor, coma, and death in twenty-four hours or longer. A fatal dose for a mouse of 22 grams weight is 0·3 gram (subcutaneously injected). In some cases the spleen is enlarged: no organisms being present, as shown by gelatine tube cultivations. Boiling for a short time diminishes the toxicity of the proteid, but does not completely destroy it, and death may result from the boiled albumoses.

(2) The *anthrax alkaloid* produces symptoms and lesions similar to the albumoses, but much more rapidly and severely. The animal becomes ill directly after the injection, gradually becomes more and more sluggish, and dies in coma, or, if a non-lethal dose be given, it recovers from the state of stupor gradually. After death, enormous local subcutaneous œdema is found, with congestion and sometimes thrombosis of the small veins. Peritoneal effusion is occasionally present, and the spleen is usually enlarged, dark, and congested, or simply congested without being greatly enlarged. The fatal dose for a mouse weighing 22 grams is between 0·1 and 0·15 gram, death occurring in two to three hours.

The anthrax bacillus in digesting the alkali-albumin forms (1) proto-albumose, (2) deutero-albumose, (3) an alkaloid. The alkalinity of the albumoses may explain their toxic properties, being due to the fact that the alkaloid is in a "nascent" condition in the albumose molecule. The bacillus forms the alkaloid

from the albumose, and it is possible that the living tissues have a similar action when the albumose is introduced into a living animal.

Entomological Society, May 7.—Captain Henry J. Elwes, Vice-President, in the chair.—Mr. H. Goss, the Secretary, read a letter from the Vicar of Arundel, asking for advice as to the course to be taken to get rid of the larvæ of a beetle which were destroying the beams of the parish church. Mr. C. O. Waterhouse said he had already been consulted on the question, and had advised that the beams should be soaked with paraffin oil.—Dr. Sharp exhibited specimens of *Caryoborus lacerdæ*, a species of *Bruchidæ*, and the nuts from which they had been reared. He stated that these nuts had been sent him from Bahia by the late Señor Lacerda, about six years ago, and that one of the beetles had recently emerged, after the nuts had been in this country for five years. Dr. Sharp also exhibited several specimens of Diptera collected by Mr. Herbert Smith in St. Vincent, and read a letter from him to Mr. Godman on the subject of the vast number of species of this order which he had recently collected in that island. Mr. McLachlan, F.R.S., Dr. Mason, Mr. Waterhouse, and Captain Elwes took part in the discussion which ensued.—Mr. R. F. Lewis, on behalf of Mr. W. M. Maskell, of Wellington, New Zealand, exhibited and read notes on about twenty-five species of *Coccidæ* from that colony. He also exhibited some specimens of the larvæ and imagos of *Icerya Purchasi*, Maskell, obtained from Natal, where the species had proved very destructive to orange, lemon, and other fruit-trees. He also showed specimens of the larvæ of an allied species from Natal, originally assigned by Mr. Douglas to the genus *Ortonia*, but which Mr. Maskell was inclined to regard as a new species of *Icerya*. Mr. McLachlan and the Chairman commented on the interesting nature of the exhibition, and the importance of a knowledge of the parasites of injurious insects, in connection with which special mention was made of the researches and discoveries of Prof. Riley.—The Secretary exhibited, on behalf of Mr. T. D. A. Cockerell, of Colorado, a large collection of insect-galls, and read a letter from Mr. Cockerell on the subject. Dr. Mason said he should be happy to take charge of these galls, with a view of rearing the insects and reporting the results.—Mr. W. H. Bates, F.R.S., communicated a paper entitled, "On New Species of *Cicindelidæ*."

Royal Meteorological Society, May 21.—Mr. Baldwin Latham, President, in the chair.—The following papers were read:—Rainfall of the globe, by Mr. W. B. Tripp. This was a comparative chronological account of some of the principal rainfall records. The earliest record is that of Paris, which commenced in 1689. The English records began in 1726. The rainfall observations in the southern hemisphere do not extend over a very long period; at Adelaide they were commenced in 1839, but they do not go back further than 1866 for New Zealand. The greatest fall in any particular year at the stations given by the author was 160·9 inches at St. Bernard in 1839, and the least 3 inches at Sandiego in California in 1863. By combining the stations in the northern and southern hemispheres the author finds that in recent times the years with the highest average rainfall were 1878, 1879, and 1883, and the years with the lowest average were 1854 and 1861.—Mutual influence of two pressure plates upon each other, and comparison of the pressures upon small and large plates, by Mr. W. H. Dines.—On the variations of pressure caused by the wind blowing across the mouth of a tube, by Mr. W. H. Dines. In these two papers the author gives the results of some experiments on wind pressure which he has made mostly on a whirling machine at Hersham, Surrey. From these experiments it seems probable that a decrease of pressure per square foot with an increase of size of plate may be taken as a general rule.

Geological Society, May 14.—Dr. A. Geikie, F.R.S., President, in the chair.—The following communications were read:—The so-called Upper Lias Clay of Down Cliffs, by S. S. Buckman. The blue clay of Down Cliff, Dorset, which has been referred to the Upper Lias, has yielded Ammonites of the genus *Dumortieria* to the author, notably *D. radians*. This blue clay is *below* the Yeovil Sands; but the position of *D. radians* in the Cotteswolds is in the limestone *above* the Cotteswold Sands, which has been placed in the Inferior Oolite series. The author, by combining the Down Cliffs and Chideock Hill sections, obtains a sequence of beds from the Middle Lias to the top beds of the Inferior Oolite, including the zones of *spinatum*, *commune*, and *falciferum*, *jurense*, *opalinum*, *Murchisonæ*, *concavum*, and *Parkinsoni*. The genus *Dumortieria* binds the *opalinum* and *jurense* zones together; while at Symondsbury Hill the author has found *Ludwigia Murchisonæ* and *Lioceras opalinum* in the same bed, which renders it difficult to draw a line of demarcation between Lias and Oolite at the top of the *opalinum* zone. The facts adduced in the paper furnish additional evidence of the untrustworthiness of a grouping which depends upon lithological appearances, and it was because no satisfactory line could be drawn between Lias and Oolite that the author, in a previous paper, supported the continental plan of grouping Upper Lias and part of the Inferior Oolite under the term Toarcian upon palæontological grounds. In the present paper he furnishes further statements in support of this view. After the reading of this paper some remarks were offered by Mr. H. B. Woodward, Mr. Hudleston, and the President.—On some new mammals from the Red and Norwich Crags, by E. T. Newton.—On burrows and tracks of Invertebrate animals in Palæozoic Rocks, and other markings, by Sir J. William Dawson, F.R.S.—Contact-alteration at New Galloway, by Miss M. I. Gardiner. Communicated by J. J. H. Teal.

Zoological Society, May 20.—Prof. W. H. Flower, F.R.S., President, in the chair.—Mr. Gambier Bolton exhibited a series of photographs, principally of animals living at the Society's Gardens and in Mr. Walter Rothschild's menagerie.—Prof. Flower exhibited a photograph of a nest of a Hornbill (*Toccus melanoleucos*), taken from a specimen in the Albany Museum, Grahamstown, in which the female was shown "walled in."—A communication was read from Sir Edward Newton relating to the reported discovery of Dodo's bones in Mauritius in 1885, by the late Mr. Caldwell. It appeared that there had been some error in the matter, and that the bones discovered were not those of the Dodo.—Mr. Sclater, F.R.S., pointed out the characters of a new Toucan of the genus *Pteroglossus* from the Amazons, proposed to be called *P. didymus*.—Mr. R. Lydekker read a paper describing some bird-remains from the cavern-deposits of Malta. These remains indicated a Vulture larger than any existing species, which, from the characters of the cervical vertebræ, he referred to the genus *Gyps*, under the name of *G. melitensis*. They also comprised some bones of a crane, of the size of *Grus antigone*, for which the name *Grus melitensis* was proposed.—Dr. Hans Gadow gave an account of some cases of the modification of certain organs in Mammals and Birds which seemed to be illustrations of the inheritance of acquired characters.

EDINBURGH.

Royal Society, May 19.—After the reading of some obituary notices, Prof. Crum Brown read a paper written by himself and Dr. J. Walker on the synthesis of sebacic acid.—Prof. Tait communicated a note on some remarkable quaternion formulæ.—Dr. Alexander Bruce read a paper on the roots of the auditory nerve and their connections.

PARIS.

Academy of Sciences, May 19.—M. Hermite in the chair.—Experiments on the deformations experienced by a spheroidal envelope subjected to pressure; possible applications to the terrestrial globe, by M. Daubrée. From the experiments described in this and in a previous communication, it appears that the author has been able to produce in various spheroids configurations like those exhibited by the earth's crust. He finds that the southern parts of the three continental masses are not deviated towards the east because of the influence of the earth's rotation, but by the effect of simple torsion in a spheroidal heterogeneous envelope subjected to contraction, similar reasoning is extended to explain characteristic canals of Mars.—New method of calculation for the interpolation and correction of meteorological observations, by M. Marc Dechevrens. The interpolation formula generally used in researches into the laws of variations of meteorological phenomena, and due either to Bessel or Fourier, is long and tedious. From considerable use of this method the author has found that it may be simplified, and in the memoir presented shows how arithmetic—multiplication and addition—may replace trigonometry, angles and logarithms.—Observations of Brooks's comet (*a* 1890) made with the great equatorial of Bordeaux, by MM. Rayet and Courty. Measures of position are given. A photograph of the comet was obtained on May 15 with an exposure of one hour. It appears on the negative as a disk having a sensible diameter,

surrounded by nebulosity, and connected with a head about 2′ long.—On the asymptotic value of the polynomials of Legendre, by M. Stieltjes.—On the determination of a point, by M. Hatt.—On the isomeric states of chromic bromide, by M. A. Recoura. The author shows that, just as in the case of the chloride, two sesquibromides may be prepared which on treatment with alkaline hydrates both yield the chromic hydrate belonging to the series of violet chromic salts. He gives a method for the preparation of the green salt in crystals of the composition Cr_2Br_6, $12H_2O$; these crystals are stable when solid, but the salt changes into the violet modification rapidly when in solution. The heat of combination of the green salt (in solution) with NaOH is given as 33·1 cal., whereas that of the violet salt is but 21·6 cal.; during the transformation from the green to the violet modification 11·5 cal. are disengaged.—On the existence of a crystallized hydrated ferric oxychloride, and its transformation into a dimorphous variety of göthite, by M. G. Rousseau. By prolonged heating of a concentrated solution of ferric chloride, in the presence of a little calcium or magnesium carbonate, in a sealed tube, crystals are obtained of the formula Fe_2Cl_6, $2Fe_2O_3$, $3H_2O$. In boiling water a reaction occurs which may be expressed thus—

$$Fe_2Cl_6,\ 2Fe_2O_3,\ 3H_2O + nH_2O = 3(Fe_2O_3,\ H_2O) + 6HCl + (n-3)H_2O;$$

the body Fe_2O_3, H_2O possessing the composition of göthite and only differing from the latter in some of its physical properties.—On some new double chromates, by MM. M. Lachaud and C. Lepierre. Double chromates of lead with potassium, lithium, and sodium are described, similar products being obtained in the case of each of the alkaline metals. Yellow bodies of the composition $PbCrO_4$, M_2CrO_4, and orange compounds of the formula $PbCrO_4$, M_2CrO_4, $2PbO$, have been prepared.—On the crystallization of alumina and some other oxides in hydrochloric acid gas, by MM. P. Hautefeuille and A. Perrey.—Note on the *bouquet* of wines and brandies, by M. A. Rommier. It is shown that different ferments produce from the same grapes wine of different flavour, and that solutions of sugar fermented by means of the natural ferments obtained from different districts yield on distillation alcohols possessing different odours; and it is suggested that the characteristic bouquet is due to a compound ether formed from the alcohol combined with a fatty acid produced from the fat which each ferment manufactures from the sugar for its own use.—On the clinical characters of true intermittent fevers; the law and preventive treatment of relapses, by M. Alcide Treille. The author gives his method of treatment by sulphate of quinine, which he has used in fever cases in Algiers for about twenty years.

BERLIN.

Physiological Society, May 9.—Prof. du Bois Reymond, President, in the chair.—Dr. Löhers spoke on the effect of inhalations of bromethyl and nitrous oxide on the circulation and respiration, deduced from experiments made with a view to obtaining a physiological basis for the use of these anæsthetics. Bromethyl slows the respiration, leaving the inspirations unaltered, but rendering the expirations weaker and weaker, until they disappear entirely; at an early stage of its action respiration becomes again normal if the animal is supplied with fresh air, but later on this is not the case, and death ensues by the action of the drug on the heart. The effect on the circulation is to quicken it at once; the blood-pressure falls, the pulse becomes arhythmic, and finally ceases; the left side of the heart is now found to be empty, the right gorged with blood: it appears that bromethyl affects the two halves of the heart differently, and thus probably gives rise to the asymmetry of the pulse. When the vagi are cut the effect of the drug on both circulation and respiration is longer in making its appearance. Nitrous oxide has a more powerful action on respiration, the inspirations diminishing rapidly and ceasing suddenly. Normal respiration may be restored by fresh air if the action of the drug has not been too prolonged. The effect on the heart is to increase the blood-pressure. It appears on the whole that bromethyl must be more cautiously employed than nitrous oxide as a narcotic.—Dr. Blaschko made a further communication on the architecture of the skin.—Dr. Löwy gave an account of experiments upon the irritability of the respiratory centre. The experiments were conducted on human beings in such a way as to discriminate between the effects of varying irritability of the centre and varying strength of stimulus applied to it in determining variations in the magnitude of the respiratory movements. The stimulus used was carbonic acid gas mixed in definite proportions with the inspired air. It appeared that dyspnœa did not supervene with less than 6 per cent. of CO_2 in the air; and that in the various states of sleep, whether natural or resulting from narcotics, and after the administering of alcohol and camphor, equal increments of CO_2 lead in all cases to an equal increase of the respiratory movements; hence in all these conditions the irritability of the centre must have been the same. Morphia, on the other hand, lessens the irritability.—Prof. Gad stated that he had some years ago observed a capillary network among the cells of the epithelium which covers the floor of the fourth ventricle, and that Retzius had observed a similar case in the internal ear. It now appears that the occurrence of blood-vessels between the cells of an epithelium is extremely rare, and he therefore urged morphologists to keep a look-out for and to investigate any cases which they may observe.

TEA IN JAPAN.

Researches on the Manufacture of Various Kinds of Tea. Bulletin of the Imperial College of Agriculture and Dendrology. By Y. Kozai, Assistant in the Agricultural Chemical Laboratory. (Tokio, 1890.)

Y. KOZAI is a Japanese chemist who performed his researches under the control of Dr. Kellner, the Director of the Chemical Laboratory at Tokio. His paper includes the chemical constitution of tea, the effect of tea on mankind, the principal methods of manufacture employed in Japan, and the methods of preparing tea for consumption. These subjects are all treated mainly from the point of view of the analytic chemist. The author appears fairly well acquainted with what the German chemists have done in the matter of tea.

We need not abstract much of his account of the constitution and properties of tea, as it is largely taken from European sources. "The chief action of tea, after it has got into the blood, is to excite the nervous system; it thus harmonizes the mind, drives out drowsiness, and awakens thought, stops hunger, and cures repletion, refreshes the body, and prevents head-ache"—and (it might be added) if taken too strong keeps you awake half the night. As to its constitution, tea contains (besides the common plant-constituents) theine, a volatile oil, and tannin. Theine is a rank poison, in toxic doses causing convulsions and paralysis, in lethal doses death; but in small quantities is (like strychnine) a delicate tonic. Of the volatile oil, Y. Kozai can affirm little beyond its well-known exciting action upon the organs of taste and smell; nor is it easy to follow it analytically through the processes of manufacture; the hot steaming employed (at near boiling temperature) in the green-tea manufacture does not appear to diminish the volatile oil sensibly, though Y. Kozai intimates that preparing green tea by boiling does dissipate the aroma. As to the properties of tannin, it is an astringent remarkable for its strong affinity for the albuminoids; hence, if taken in excess, it may, by precipitating the ferments of the digestive fluids, cause indigestion.

The account of the chief Japanese methods of manufacture is of more interest and instruction to the European planter.

We may premise that there are two (main) kinds of tea, viz. black and green. In the manufacture of black tea there are four essential processes, viz. (1) withering; (2) rolling, (3) fermenting, (4) drying. In the manufacture of green tea, the fermenting is omitted, and in Japan (for some kinds of green) the rolling also.

For the manufacture of black tea there is no real difference between the Japanese method and that practised by English planters in Bengal. The fresh picked leaf (*i.e.* tips of the young shoots) must be first withered, or the petioles and leaves break under the rolling; the exposure of an hour or two in strong sun withers the leaf sufficiently; if there is no sun, the leaf must be withered by the aid of fire-heat. The rolling is done, even in Japan, by the aid usually of a box, and in Bengal often by steam-power (and very roughly). The juices are thus expressed, and the leaf given a "nice" twist, *i.e.* a twist pleasing to the fancy of the tea purchaser. What perhaps renders rolling so essential in the manufacture of black tea (for it is not esssential in the manufacture of green), is that it masses the leaf in a state conducing *without delay* to fermentation. Neither Y. Kozai nor the best Bengal authorities like to lose the juices more than can be helped. He also hazards the view that, by rolling, the juice is expressed from the cellular tissues of the leaves and impregnated upon their surface; thus is produced fine aroma, and the leaves are more easily infused. Fermentation is the most important point in the manufacture of black tea, and by it (*fide* Y. Kozai) the leaves lose their raw smell, and the tea acquires its fine flavour. The fermentation is really only carried a very little way: Y. Kozai says it should be allowed, in a temperature of 104° F., to proceed only for about an hour. He thinks the process is a true fermentation, because if permitted to run too far the tea acquires an acid taste. He thinks it probable that the ferment is caused by a living organism, but he adduces very slight ground for this opinion; and it has, in fact, been questioned whether there is any true fermentation in the process at all. But the English tea-makers are agreed with the Japanese in the importance of stopping the fermentation exactly at the proper point by drying the tea, which is usually done by placing it first in the sun and turning it over till it is fairly dry, and then thoroughly drying it by fire-heat.

The result of all the Bengal experience is that the black tea is at least as good when these four processes are done simply and rapidly, as when much labour and time are expended in complicating them. In the early days of tea manufacture by Anglo-Indians, great pains were taken to imitate with tedious minuteness the careful hand-processes (and repetitions of portions of the processes) as practised in China; but all planters now follow rapid short cuts to the finished tea.

The manufacture of green tea is nothing more than drying the leaf; it is so little practised in British India as to be of no commercial interest there, but Y. Kozai describes in detail three kinds of green tea manufactured in Japan.

(1) *Japanese* (not China) *green tea.* In this, the leaf is steamed in order to remove the raw flavour; it is then rolled and fire-dried, the two last processes being usually done together.

(2) *Chinese green tea.* In this, the leaf is roasted (while stirred with a stick) in an iron pan over a fire, then rolled a little, then roasted again; these processes being repeated even six or eight times, and the tea is then finally dried off.

(3) *Flat tea*, the highest class tea of all. For this tea, the shrubs are usually kept shaded for three weeks before picking, so that the leaf is partly etiolated. The choicest leaves are selected before the manufacture is commenced. They are steamed, but never rolled; nor, indeed, touched by hand at all, but carefully turned by the aid of a bamboo stick. After sufficient steaming they are simply dried.

The author finds by analysis that there is ·30 per cent. more theine in etiolated leaves than in the leaves of the same plants grown in the light. He tried many experiments to test the chemical effect of the manufacturing

 G

processes. Among other tables given by him is the following; a quantity of leaf was divided into three portions, whereof one portion is A, another portion is manufactured into green tea B, the third portion is manufactured into black tea C. Y. Kozai analyzses A, B, C, and finds—

	A.	B.	C.
Crude protein	37·33	37·43	38·90
Crude fibre	10·44	10·06	10·07
Ethereal extract	6·49	5·52	5·82
Other nitrogen-free extract	27·86	31·43	35·39
Ash	4·97	4·92	4·93
Theine	3·30	3·20	3·30
Tannin	12·91	10·64	4·89

He remarks that the general result of the green-tea manufacture is merely to dry the leaf; the black-tea manufacture alters materially its chemical constitution. The principal change is the remarkable diminution of the tannin. He does not explain how this is brought about, nor is it easy to see how the incipient fermentation should affect the tannin.

The only teas exported to Europe from Japan are of low class; they are frequently "faced," and sometimes mixed with the leaves of various Japanese plants. Any plentiful leaf, not too unlike the leaf of tea, will do for this adulteration; the leaves actually employed are (Y. Kozai assures us) all harmless, and several contain tannin, but none of them any theine. As to the "facing," he says it can hardly be called adulteration; the quantity of Prussian blue employed to improve the appearance of green tea is (according to Y. Kozai) about 0·001 per cent. the weight of the tea, perfectly innocent, and pleasing to a purchaser.

The author concludes with an account of the different ways of taking tea in Japan, with some analyses of the prepared liquor.

(1) In the case of flat tea, or of the very finest quality of Japanese green tea, the tea is ground to fine powder, and the whole infusion drunk.

(2) In the case of superior (*i.e.* from the Japan point of view) tea, the leaves are infused for two minutes in water at 120°–150° F.

(3) In the case of a medium tea, the leaves are infused for one minute in boiling water.

(4) In the case of inferior tea, the leaves are boiled in water.

The object to be aimed at in the preparation is to get the largest possible quantity of theine without dissipating the aroma, and accompanied by only a moderate amount of tannin. Y. Kozai gives analyses to show that this is effected (in the case of superior teas) by the infusion in water at 120°–150° F. for two to five minutes. By superior teas, he understands teas worth five to seven shillings a pound in Japan. It is probable, therefore, that the highest class teas we ever have to deal with in England come under the medium teas of Y. Kozai, which require infusion in boiling water—for one minute at least. The majority of English people like a good deal of chicory with their coffee, and probably a majority also like a good deal of tannin with their tea; and to them the analyses and recommendations of the Japanese writer are of small importance.

The paper will be of more use as food for reflection to the Anglo-Indian planter than as direct instruction. The palate of the Englishman is as yet only very roughly educated in tea. There can be very few Englishmen who would greatly prefer the superior teas of Japan and China to the ordinary Kumaon or Ceylon tea; most persons used to drinking the latter would probably prefer it to the most expensive tea made—say China tea worth forty shillings per pound in China. The English planter in Bengal has a tea-garden of 200 acres (possibly still larger). His object is, by the aid of a steam-engine or other coarse help, to put his tea through—to keep his factory clear when he has a strong flush on. He has to carry the daily make through by the aid of uncivilized labourers and overseers. He must reduce every step of his manufacture to a routine; he must have no special tea separately and differently manufactured, and no current experiments. Few planters have made much profit by Pekoe; and the green tea hardly exists commercially in India. There are no doubt many Englishmen who, having not a plantation but (literally) a garden with some tea in it in India, have manufactured, not unsuccessfully so far as the flavour of the tea is concerned, green tea, Pekoe, &c., but this has been a fancy article for their own drinking or for presents, and has never been put in any quantity on the market. To plant successfully in India, the Englishman has to proceed on a broad scale; his large cost and high expected profit cannot be got out of the close superintendence of elaborate hand manufacture. Or, at least, it will be a long time before the public tea taste at home is sufficiently elevated to be willing to pay so large a price for such teas as would remunerate the English planter. For the present, the object of the planter must be to produce the maximum quantity of tea that the English grocer can sell at 1*s.* 6*d.* to 2*s.* 6*d.* a pound. Hence to planters the utility of the paper of Y. Kozai must be mainly future.

CATALOGUE OF BRITISH FOSSIL VERTEBRATES.

A Catalogue of British Fossil Vertebrata. By Arthur Smith Woodward and Charles Davies Sherborn. Pp. i.–xxxv., 1–396. (London: Dulau and Co., 1890.)

A WANT long felt by all students of the fossil Vertebrates of the British Islands has been supplied by the issue of the present volume, which, so far as we have been able to examine it, is noteworthy alike for the absence of misprints, the accuracy of the references, and the care which has been taken in the selection of the correct names for the various genera and species, as well as for the orthography of the names themselves. The last edition of the late Prof. John Morris's "Catalogue of British Fossils" was published as far back as 1854, and the advances made by this branch of palæontology since that date—and more especially during the last ten years—have naturally rendered that work quite out of date. It is true, indeed, that the first part of Mr. R. Etheridge's "Catalogue of the Fossils of the British Islands," and the British Museum Catalogues of Fossil Vertebrates, have afforded some assistance to students of this subject;

but since the former deals with the Vertebrates of one particular epoch, while some of the latter include only such of the British fossil Vertebrates as are represented in the National Collection, they in no way cover the ground occupied by the present work.

It is, of course, needless to say that the work before us is essentially a technical one, and therefore appeals only to students of this particular branch of science, or to those stratigraphical geologists to whom it is important to know the correct horizon, localities, and nomenclature of the fossil Vertebrates of the British strata. So far as completeness and accuracy are concerned, the work is beyond criticism; but we trust we shall not be accused of any carping spirit if we venture in the course of our notice to indicate a few points in which, according to our judgment, it might be improved.

The greater part of the introduction is occupied by an entirely new and very valuable history of the chief collectors and collections of the fossil Vertebrate remains found in the British Isles. Then we have a careful explanation of the general plan of the work; followed by some judicious remarks as to the harm that has been done to the science by the publication of a host of undefined names. When, however, the authors hold "a single University Museum" "responsible for no less than seventy meaningless terms," we venture to think that the individual or individuals by whom such names were proposed should rather have been held responsible for the same. Following the introduction, a table (for which the authors are indebted to Mr. W. H. Brown) of the dates of publication of the fasciculi of Agassiz's "Recherches sur les Poissons fossiles" will be found of especial value, as fixing the date of many genera of fossil fishes. Scarcely less valuable is the determination of the respective dates of appearance of the three parts in which Sir R. Owen's well-known "Odontography" was originally issued.

In the table of the stratigraphical distribution of British fossil Vertebrate genera, which concludes the prefatory portion of the volume, we must take exception to the very insignificant deposit known as the "Forest-bed" being allowed to take rank as the *Forest Bed Series*, as though it were of equal importance with the Pliocene and Pleistocene; under one of which it should have been included as the *Forest-bed Stage*.

In regard to the plan of the work itself, the various genera and species are arranged alphabetically under the classes to which they respectively belong—a mode of arrangement in which the authors follow the Morrisian Catalogue. They depart, however, from the latter in not mentioning the order to which each genus is commonly referred. Here, we think, the innovation is not an improvement, since in the case of stratigraphical geologists, who may have occasion to consult the work, it would often be an advantage to know at once to what large group any particular genus belongs; and even a student of one particular class of Vertebrates may well be at a loss to know the ordinal position of a genus belonging to another class with which he is less intimately acquainted.

It also strikes us that it would have been advisable to state the authority for regarding various genera and species as synonyms of others; for, as it stands at present, there is no evidence to show whether such references are made for the first time on the authority of the authors themselves, or whether others are responsible. Thus, under the head of *Hyracotherium leporinum* (p. 356) we find *Pliolophus vulpiceps* given as a synonym, without any guide to the authority for such reference. In this particular instance we believe the identification of *Pliolophus* with *Hyracotherium* was first made by Prof. W. H. Flower in his article "Mammalia," published in 1882 in the latest edition of the "Encyclopædia Britannica," and some reference to this should have been made.

On the whole, the authors appear to have exercised a wise discretion in not amending for the first time the spelling of such generic and specific names as are obviously incorrect according to a true Latinized orthography. We cannot, however, follow them in their refusal to accept emendations which have already been published in other works, more especially as they are not consistent in either adopting or rejecting such emendations. Thus, for instance, they adopt the name *Machærodus* (p. 366) as amended from the original *Machairodus*; but they refuse to accept *Ælurus* in place of *Ailurus* (p. 311), although the amended name has been published more than once.[1] Again, they retain *Leiodon* (p. 245) and *Platecarpus* (p. 264), although the amended *Liodon* and *Platycarpus* have been published—the latter, we admit, but recently. The authors seem, indeed, to have a rooted objection to the transliteration of the Greek ει into the Latin *i* (as may be noticed in the root *Cheir* instead of *Chir* under the head of Pisces); but this transliteration, as every student of our Greek Testament knows, is just as binding as that of αι into *æ*, or ου into *u*, and if the one change is rejected the others ought not to be adopted.

As a rule, the authors have paid attention to the gender of generic names, which is too often neglected. They regard compound generic names as substantives, and, therefore, bring the gender of the specific name into accord with that of the terminal portion of the generic one. They state, however, on p. 395, that they have not followed this rule in regard to names ending in *lepis*, where they have allowed the specific names to remain with the masculine termination. They appear to have adopted the same course with regard to the termination *batis* (*Aëtobatis*, p. 9); but in the case of *aspis* the authors seem to have been unable to make up their minds, since on p. 79 we find *Eukeraspis pustuliferus*, while on p. 129 we have *Odontaspis cuspidata*.

As features of especial value in the work before us, we may notice that in every instance where it can be ascertained the place of preservation of the type specimens is indicated; while all the recorded localities are given under the head of the various species.

The compilation of a work like the present is a labour which only those who have had the misfortune to try it can fully comprehend, and the thanks of every student are therefore due to Messrs. Woodward and Sherborn for the production of a book which is absolutely indispensable to all those who are engaged in the pursuit of this branch of palæontology.

AN EPHEMERIS.

Connaissance des Temps. Extrait à l'usage des Écoles d'Hydrographie et des Marins du Commerce. Pour l'an 1891. (Paris: Gauthier-Villars et Fils, 1889.)

THE *Connaissance des Temps* has, within the last few years, by successive improvements, been made quite the most convenient Ephemeris for general use. The information it contains is conveniently given, and almost excessive in amount; and the result of course is that the pages of tabular matter are a good deal crowded, in order to make the annual volume of reasonable size. For travellers whether by sea or land it, like our own *Nautical Almanac*, is not, however, quite what is wanted. Much of the information it contains is of no use to them, and the size and weight of the book is excessive for their purposes. This appears to have come to the notice of the Ministry of Marine, who, in 1887, directed the publication of a pamphlet of extracts from the *Connaissance* containing the necessary information for Navigators and students for certificates as Masters, a copy of which is now before us.

In making this effort to meet the wants of a very large class of practical men the French have but followed the example of other countries. Some forty years ago the Prussian Government caused to be compiled a *Nautisches Jahrbuch*, which in its present form appears to be the best adapted of those we have seen for geographers and voyagers. It is manifestly copied, as to form, from the *Nautical Almanac*, avoiding all the matter useless to geographers, which is relegated to the well-known *Berliner Jahrbuch*; the contents are all given with an accuracy sufficient for the purposes for which it is intended: a thoroughly practical mind seems to have guided the whole arrangement, and the changes which seem desirable are but small. The American Government next published an *American Nautical Almanac*, which is practically a reprint of those parts of their larger Ephemeris which are supposed to be required at sea. It is needlessly accurate in its data, and needlessly bulky, but no doubt fulfils its object. And again, just before the French, the Austrian Government published at Trieste a Nautical Ephemeris founded on our *Nautical Almanac*, but almost identical in contents with that of the German Government before spoken of. This, it would seem, is published with the text and headings in more than one language.

The French work approaches most nearly in type to the American: it is mainly a reprint. That part which is not so is the Ephemeris of the Moon, and here convenience is sacrificed to a small gain of space. Not only are the pages crowded unduly, but the arguments (being at 12-hour intervals) are so far apart that interpolation becomes inconvenient.

Before closing we would like to point out that while all these Governments have provided an Ephemeris for their Nautical men and Travellers which is meant to be specially suited to their limited wants; England alone, which owns probably half the sea-going ships in the world, and furnishes no small proportion of the explorers, makes no special provision for them. It is not that there is no want felt: for there are several almanacs which, availing themselves of the *Nautical Almanac*, give astronomical data, together with various other matters useful to seamen. Our *Nautical Almanac* took its present form on the report of a committee of the Royal Astronomical Society, to whom reference was made by the Admiralty in 1830. No great change has been made since then, and it is beginning to be thought time that its contents should be revised: if this is done, we trust it may be considered whether the wants of navigation and geography should not be specially taken into account. If we are right in believing that the Austrian Government have founded on our *Nautical Almanac* a publication which admits of all the tabular matter, which is so difficult and expensive to put in type, being combined with a text in varying languages, it might be possible by the adoption of a suitable form, to supply the wants of other nations as well as our own. Our *Nautical Almanac* in its present form is used, we believe, extensively by those maritime peoples who adopt Greenwich as a prime meridian, and it would, we think, not be difficult to arrange with their Governments for impressions suited to each language.

OUR BOOK SHELF.

The Wimshurst Electrical Influence Machine. By W. P. Mendham. (Bristol: King, Mendham, and Co., 1890.)

THIS little book, which partakes somewhat of the nature of a trade catalogue, briefly describes and illustrates the construction and action of the Wimshurst machines made by the firm of King, Mendham, and Co., and of the accessory pieces of apparatus needed for use with these machines in performing the antiquated experiments so much in vogue with the dabbler in frictional electrical science. The study of high tension electricity is coming to the front so much just now, that it is a great pity Mr. Mendham has not utilized his opportunity better, and given to the class of readers for whom this book is intended some notion of the many instructive and easily performed experiments on the disruptive discharge, and on electrical oscillations, which we owe to Hertz, Lodge, and others. The only concessions made to modern discoveries are in the descriptions of apparatus to show the action of the electric discharge on smoke, and of the Thomson quadrant electrometer. The latter, however, had better have been left alone, for the description is too meagre to enable the action of the instrument to be appreciated, and the reader may be apt to imagine that the quadrants are intended to be connected up directly to the terminals of a Wimshurst machine. We need scarcely say this would be very hard on the instrument. H. H. H.

Pawnee Hero-Stories and Folk-Tales. By George Bird Grinnell. (New York: Forest and Stream Publishing Company, 1889.)

THE Pawnees were at one time what Mr. Grinnell calls "a great people." They roamed over a vast territory, and enjoyed considerable material prosperity. Now, their numbers are greatly reduced, and the few who remain give a very inadequate idea of the vigour of the original stock. The author of the present book knew the tribe intimately twenty years ago. He used to camp and hunt with them in Nebraska, and at night they told him hero-stories and folk-tales which had been handed on to them from their forefathers. Many of these narratives he carefully translated and wrote down at the time; and quite lately he visited his old friends for the express purpose of inducing them to extend his collection. They were eager to meet his wishes, and so he was able to bring together the stories which he has now published. He claims that they are recorded exactly as he himself

heard them, and that they may therefore be regarded as faithfully reflecting the Pawnee character. As genuine documents, throwing light on the ideas and habits of a primitive people, the stories are of some scientific value; and students of anthropology will find in them a good deal that is interesting and suggestive. Mr. Grinnell adds various notes, in which he gives much well-arranged information as to the history, racial affinities, and institutions of the Pawnees.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Influences at Work in producing the Cerebral Convolutions.

DR. G. JELGERSMA, of Meerenberg, has recently published two remarkable papers,[1] in which he endeavours to explain the influence which leads to the production of the convolutions on the surface of the cerebrum and cerebellum. Many theories have been advanced to account for these. Several authorities have ascribed their presence to mechanical forces operating upon the brain from without, whilst others have sought to explain them by the supposition of different degrees of growth-tension acting upon the brain-surface; but in every case these theories, when submitted to the test, have broken down, in so far that it is impossible, by means of any of them, to show how it comes about that small animals have smooth brains, and large animals convoluted brains; how, in short, we should find in the beaver —an animal remarkable for its intelligence—a cerebrum almost entirely smooth, and in the sheep—an animal, shall we say remarkable for its dullness?—a brain with a high convolutionary system. Jelgersma not only explains this, but makes the apparent discrepancy the strongest pedestal of support to his theory. Briefly put, his views are as follows:—

The grey cortex of the cerebrum, which in different forms of the same animal group preserves a tolerably constant thickness, increases by surface extension. Now, if we extend the surface of a smooth-brained animal say four times, we must provide eight times as much white matter to fill the interior of the grey capsule, if we desire to keep the surface even; or, to put it in different terms, if we lengthen out the radius of the brain say ten times, we acquire a surface extension one hundred times greater, and an internal capacity one thousand times greater. The geometrical law involved is simply this, that in the growth of a body the surface increases with *the second*, but the interior with *the third* power of the radius.[2]

Such being the case, it is very evident, seeing that the proportion of internal white matter and external grey matter is in all cases a uniform one, that in the evolution of a large animal out of a small animal, a disproportion between the grey capsule and the white core of the cerebrum must result. This is compensated for by the extended cortex placing itself in folds or puckers, and thereby reducing the capacity of the capsule to a degree which brings it into correspondence with the white contents. Consequently, "the formation of the convolutions and furrows is simply the result of the tendency on the part of the superficial layer to increase by surface extension and of a mutual space-accommodation (*Raumaccommodation*) of the grey substance and of the white conducting paths."

I have not written this short account of Jelgersma's views—important though they be—simply for the purpose of giving them a wider circulation through the pages of NATURE, but with the object of stating that the theory advanced has received independent testimony in its favour at the hands of my colleague, Prof. George F. Fitzgerald. For two years or more I have been engaged in a research bearing upon the growth of the cerebral hemispheres, and have constantly had occasion to appreciate the unsatisfactory nature of the current theories as to the formation of the convolutions of the brain. Consequently, in February last, before I had read Jelgersma's first article, and before the appearance of the second, I explained to Prof. Fitzgerald, as far as I could, the conditions of cerebral development, and asked him if he could offer any geometrical explanation which would account for the appearance of the convolutions. The views which he then advanced were identical with those of Jelgersma, and further, they were expressed in very similar terms. I feel that this adds greatly to the weight of the hypothesis.

But Prof. Fitzgerald went further than Jelgersma, because the latter states that he is unable to explain why the fissures and convolutions should, within certain limits, assume the same formation in different animals. Fitzgerald, however, saw the importance of his theory in regard to the localization of function in different areas of the cerebral cortex. The surface extension of the cerebrum cannot be a uniform one: the bulgings out in the shape of the convolutions must necessarily be connected with the functions which the areas involved have to perform. Therefore if a given area of grey matter increases it must pucker out, unless an undue quantity of white matter grows all over the inside of the grey cortex.

[2] It is right to state, although, indeed, Jelgersma does not mention it, that many years ago Baillarger ascribed the increase of the convolutions with the increase in the size of the animal to the same geometrical law.

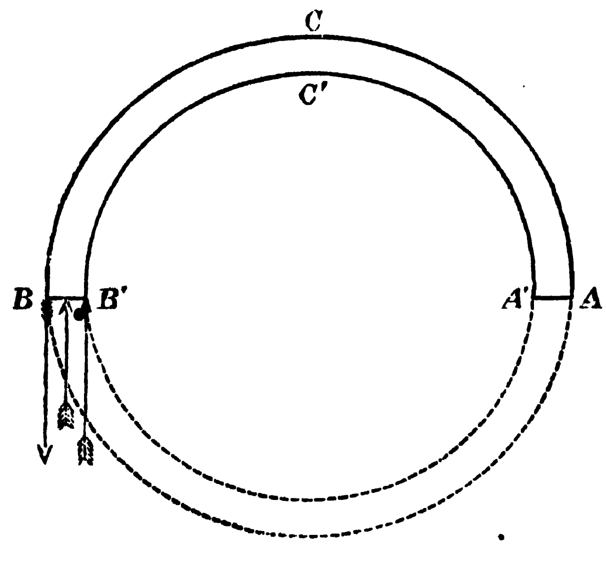
The Bourdon Gauge.

FROM Prof. Greenhill's letter on this subject in NATURE, vol. xli. p. 517, as well as from that of a writer in *Engineering*, I gather that I did not succeed by my letter (NATURE, vol. xli. p. 296) in making quite clear the point of my explanation of the action, since Prof. Greenhill argues that consideration of the longitudinal stresses in the walls leads to the conclusion that the tube would curl up under internal pressure rather than uncurl.

Towards the top of the second column on p. 296 in my letter I used the words "Consider now the equilibrium of any portion . . . when the internal pressure is applied and before uncurling takes place." Perhaps it would have been clearer to have written "*after the internal pressure has been applied,*" &c. In the last figure on the same page the tension T is that exerted by the outer wall *of the already distended gauge* as it contracts, while P is the thrust of the inner wall, each on the part BC supposed solidified.

I desire specially to emphasize the words italicized, for my method of explanation amounts to an artifice for taking the distension into account. It is because Prof. Greenhill has overlooked this that he arrives at an opposite conclusion, and wishes apparently to reverse the forces in the figure referred to.

I hope to make this clear by putting the argument again in a slightly different form.



Starting, as before, with a tube of rectangular section, with the end AA' fixed and BB' free, we arrive at the uncurled condition by taking the tube in imagination through the following series of steps:—

(1) Remove the ends AA' and BB', and complete the annulus as indicated by the dotted lines of the figure.

(2) Now apply internal pressure. This distends the tube, stretching the roof and floor. The inner wall is compressed with a longitudinal thrust, and the outer wall stretched with a longitudinal tension, but the change in the diameter AB, or in the diameter A′B′, will be practically unobservable.

The action on the original gauge and its enclosed fluid of the added part and its fluid, consists now of the forces indicated in the figure, and which amount, as I have in my previous letter pointed out, to a couple (counter-clock-wise in the present figure).

(3) Now replace the ends at AA′ and BB′ (this makes no difference in the equilibrium), and holding AA′ fixed, remove the added part.

The gauge will now uncurl, for we are removing the counter-clock-wise couple necessary to maintain equilibrium. Or, to put it in other words, the outer wall ACB, on being released from the tension at B shortens, while the inner wall being released from the pressure at B′ becames longer, thus causing the gauge to uncurl.

As to Gauss's purely geometrical theorem, I fail to see how it is to be of any use in the analysis of the forces, which I take to be the real problem. All that Gauss says to us by his theorem is, "Pure bending in your gauge means uncurling; if, therefore, you can prove that the forces are such as to produce pure bending, you prove that they produce uncurling." But this is exactly what we cannot prove. Indeed, it is admitted that the bending is not pure. And it is, I think, of no use to urge, with Lord Rayleigh, that the bending is *nearly pure* on account of the comparative inextensibility of the material, for that argument would apply equally to the gauge with both ends fixed, or to a complete annulus which obviously cannot uncurl. In fact, if we could go back to Gauss and ask, "Is it any use showing that the bending is 'nearly pure'?" he would ask us what we meant by "nearly," and before we could answer that we should have to analyze the whole action. It is for these reasons that I consider the reference to Gauss's theorem not only unfruitful but misleading.

If we apply the method I have suggested to a tube of elliptical or other than rectangular section, we see that unless longitudinal stresses such as I have dwelt upon would exist in the walls were the annulus completed, the distended gauge will not uncurl on the removal of the added part, and the only reason for considering the curvature of either wall in a plane perpendicular to the circular axis, is that such curvature may, on account of the properties of the material by which it is able to distribute stress in different directions, lead to additions to or subtractions from (and conceivably therefore reversals of) the longitudinal thrust or tension that would exist in a tube of rectangular section. But this is obviously a question of the structure of the material and not of pure geometry. A. M. WORTHINGTON.

A Subject-Index and the Royal Society.

THE following brief account of an offer I have made to the Royal Society will, I think, prove of interest to the readers of NATURE, and especially to those correspondents who have emphasized the importance of a subject-index for the progress of science in all its branches.

Upon the conclusion, last autumn, of five years' work, during which my "Epitome of the Synthetic Philosophy" was compiled, I commenced to look for some literary work which would be of undoubted *practical* service to science, and which would if possible aid its further development. The articles and numerous letters then appearing in your columns urging the importance of a subject classification of the memoirs arranged under the authors' names in the "Royal Society Catalogue of Scientific Papers," led me to discuss the advisability of my undertaking such a proceeding with several friends upon whose judgment I could rely; with the result that, one and all agreeing upon the value of such a work, I wrote to Sir G. G. Stokes, P.R.S. (to whom I was directed), offering to compile the manuscript of the greater portion of such a work upon the condition that, as soon as the manuscript was completed and approved by the Council of the Royal Society, the Society should guarantee all expenses of print and publication. I was forced to say "the greater portion" of such a work ("70 to 80 per cent."), for examination of a large number of titles had shown me that a certain percentage of them could only be correctly indexed by specialists in their own departments, a fact which is emphasized when we call to mind that a title may be in any one of eight European languages.

After several interviews with Sir G. G. Stokes, and a somewhat protracted correspondence, I agreed to arrange a sample index of some 2000 entries upon a plan suggested by him, and warmly approved by that eminent bibliographer Dr. Garnett, of the British Museum, the plan being to take the leading word or words in the title of each paper, with a reference to the volume, page, author's name, and number of the paper, in the Royal Society's Catalogue, for subsequent arrangement in alphabetical order, by which means the subject-key would occupy but a quarter of the bulk of the Catalogue as now published. It would extend—that is, approximately—to three quartos of the size of the present volumes, in similar type, &c.

In the early part of May this plan was discussed by the Catalogue Committee of the Royal Society, when the following resolution was passed:—"That the offer of Mr. Collins be declined, and that the President be requested to convey to Mr. Collins the best thanks of the Committee for the trouble which he has taken."

The foregoing account will be sufficient to show that, contrary to an opinion expressed more than once in these pages, something more is needed than an offer to compile the subject-index. Were the manuscript now completed, and approved by the Royal Society, there would still be wanting a sum sufficient to bring it before the public.

In conclusion, I should like to express my warm thanks to Sir George Stokes for the kind and courteous way in which he has assisted me in my endeavour to develop what I am still convinced would be of immense service to science in all parts of the civilized world; and not only to science, but to many industries besides. For would not the chemical manufacturer and the dyer profit by a complete list of all the papers that had been written on the coal-tar colours; the agriculturist, by knowing the researches which had been undertaken to ascertain the nutritive powers of the bones and phosphates, and the fattening properties of the various cakes and foods; the engineer, the analyses of iron and steel with their accompanying properties; the physician, the physiological action of the various drugs; and the electrician, all the papers, for instance, which had been written upon that little understood subject, induced currents? Finally, how many millions might have been saved in the construction of harbours all over the British Empire had all the scattered information upon the flow of water in rivers and tidal estuaries been so gathered together as to make reference possible, not to say easy? F. HOWARD COLLINS.

Churchfield, Edgbaston.

Stream Lightning.

IF a candle-flame is put between the poles of an electrical machine, while it is giving rough angular sparks, the discharge at once changes into a smooth single line of very easy curvature: it suggests the difference between sinuous and stream lightning: it is not merely that the spark is as if shortened by the conducting flame; the whole nature of the discharge is changed. If the flame is held two inches beneath the poles, the spark will go down to it. W. B. CROFT.

Winchester College, May 30.

Atmospheric Circulation.

ON March 9 and 10, 1887, the barometer rose to 30·92 inches over Iceland—a very exceptional height for that locality at that time of the year. The United States daily maps of the northern hemisphere show that a storm to the southward of this great anticyclone was carried westward a distance of over six hundred miles within twenty-four hours, in a manner similar to that in which West Indian hurricanes follow the course of the trade winds in August and September, although this storm was located in latitude 40° N., or in the usual situation of the anti-trades. Other instances of a similar character have been noted, but this one was unusually well defined, and throws much light upon the laws governing the atmospheric circulation.

Lyons, N.Y., May 20. M. A. VEEDER.

Testing for Colour-Blindness.

IN answer to Prof. Lodge's query (May 29, p. 100), why those concerned in testing for colour-vision do not avail themselves of instruments like Lord Rayleigh's, having tested some thousands in this city, I may state that experience has shown that they are

not suited for testing uneducated persons. A similar instrument, introduced by Chibret and Meyer, of Paris, is to be found in ophthalmic hospitals.

I may further remark that I do not consider any test satisfactory unless made by an ophthalmic surgeon, as he alone is accustomed to deal with such people every day of the week, and can alone eliminate such errors as refraction-disease and stupidity. D. D. REDMOND.

14 Harcourt Street, Dublin, May 3.

The Green Flash at Sunset.

YOUR correspondents (vol. xli. pp. 495, 538) seem to imply that this phenomenon is only seen at sea, but I observed it on May 17 while walking from east to west, near Worms Heath (Warlingham, Surrey). It had been an exceptionally fine day, since the morning, and about 8 p.m. there was not a cloud in the sky, except to westward, where strips of cloud were rapidly forming, and covering up the glow of sunset; the sun had sunk behind a hill, when, suddenly, my companion and I both saw a flash of green light against the thickest cloud; it lasted 1 or 2 seconds, just long enough for there to be no doubt about it. We compared it to the glare thrown by "green fire," extending over an area whose diameter appeared about four times that of the moon.

At 12 p.m. the same night it was raining.

I think this observation definitely negatives the sea-wave theory, while the appearance was seen at least in association with the condensation of aqueous vapour. Perhaps the reason it was not *bluish*-green was that this vapour absorbed the blue rays? T. ARCHIBALD DUKES.

16 Wellesley Road, Croydon, June 2.

THE THEORY OF SCREWS.[1]

THE book before us, a large octavo volume of over 600 pages, gives in a connected form the results of Sir R. S. Ball's investigation in the theory of screws, as contained in his "Theory of Screws" and a series of publications in the Proceedings and Transactions of the Royal Irish Academy. But as its scheme is that of a text-book on theoretical mechanics, it begins with a chapter on the postulates and methods of mechanics; whilst chapter vii. is on the theory of moments of inertia; chapter viii. on impulsive forces capable of imparting to a rigid body a given state of velocity; and chapter x., on kinetic energy, contains a number of propositions from analytical dynamics. Here expressions for the kinetic energy, for its change in consequence of an impulse, Lagrange's equations of motion in generalized co-ordinates, Hamilton's principle of least action, and various other propositions, are developed in the usual form—that is to say, without the use of screws. The rest of the book relates to the theory of screws and its applications. This alone, as forming the characteristic feature of the book, concerns us here, and of it we shall try to give an outline.

In order not to be unintelligible to those who have no knowledge of Ball's creation, it will be necessary to begin with the very elements of the subject; and in order to form a just idea of the scope and importance of the new method, it will not be sufficient to give a sketch of the results obtained—it will be necessary to take a wider view of the subject. We shall then be able to form some idea of the inherent capabilities of the theory. These I believe to be very great—very great indeed. One of its peculiarities lies in this, that all the results obtained in modern algebra and geometry, as distinct from analysis, seem to be directly applicable to it.

Friends of synthetic geometry and of graphical methods, too, will find here a wide field for investigations. Grassmann's "Ausdehnungslehre" has already been pressed into its service, and the theory of vectors and quaternions is easily applicable. Clifford, in fact, has generalized the latter theory into that of biquaternions to embrace screws.

Mr. Cartesius, to make use of Sir Robert's personifications, has been dethroned, and Mr. Anharmonic together with Mr. One-to-one reign in his place.

Poinsot, whose investigations form the starting-point of the theory of screws, has proved that a rigid body can always be transferred from one position to any other by a rotation about a certain perfectly determined axis, together with a translation along this axis. These two motions combine to a motion identical with that of a nut on a screw. It is completely determined if the angle through which the rotation takes place, together with the ratio of the translation to the rotation, is given. This ratio—*the "pitch" of the screw*—characterizes the screw. As the motion does not at all depend upon the diameter of the screw, we may suppose this to become infinitely small, and then we have the notion of Sir R. Ball's *screw*.

A screw, therefore, is a line in space which has connected with it a certain pitch—*i.e.* a certain length, as the pitch is a linear magnitude. The compound motion considered is called a "twist" about a screw, and is known if the screw and the "amplitude" of the twist, *i.e.* the amount of rotation, is given. In the same way a system of forces can, according to Poinsot, always be reduced, and that in one way only, to a single resultant and a couple turning about the resultant; and these two dissimilar parts Ball combines to a "wrench on a screw," the line of action of the resultant force being the axis of the screw and the ratio of the moment of the couple to the force giving the "pitch," whilst the magnitude of the resultant force is called the "intensity" of the wrench.

We have thus a new entity—the screw—and its introduction forms the characteristic distinction of the theory. Connected with it is a kinematical and a kinetic entity—the twist about a screw, and the wrench on a screw.

If we now consider a rigid body under the action of any forces, then the latter combine at every moment to a wrench on some screw, whilst the motion itself is always a twist about some other screw. If the body is constrained in any manner, then the reactions due to the constraint will also at every moment combine to a wrench about some screw.

The problem first to be solved is that of the combination of twists and wrenches. Let any two screws, α and β, be given, then wrenches on them constitute together a system of forces, and therefore combine to a wrench on some other screw, γ, which has to be determined. If the ratio of the intensities of the two given screws be varied whilst the screws themselves remain unaltered, then the screw, γ, of the resultant wrench also varies, and its axis describes a surface called the cylindroid. This is a ruled cubic surface which can be described as follows:—Let through a fixed line, l, a plane be drawn, and in it a circle be taken. Let a point, P, move uniformly in the circumference, whilst the plane itself turns uniformly about l, completing half a revolution whilst P describes the whole circumference. The perpendicular from P to l will then generate the cylindroid, and the screw on any generator will have a pitch equal to the length of the perpendicular from P to l. The line l is a nodal line of the surface and perpendicular to all screws on it. All cylindroids are similar, and through any two screws one cylindroid can always be drawn. The projections of all generators on a plane, perpendicular to the nodal line, form a flat pencil in which each ray corresponds to one screw. Also to each point on the circle corresponds one screw. We may here mention that this generation of the cylindroid stands in a very close relation to the plane representation of the cylindroid which is given in chapter xx. For if A, B are the ends of the diameter of the above circle which is perpendicular to the nodal line l, then to A and B correspond two generators of the cylin-

[1] "Theoretische Mechanik starrer Systeme auf Grund der Methoden und Arbeiten, und mit einem Vorworte von Sir Robert Ball, Royal Astronomer of Ireland." Herausgegeben von Harry Gravelius. (Berlin: Georg Reimer, 1889.)

droid which meet at right angles. Let the corresponding screws be α and β. Then if the circle when in a plane with α be turned about its diameter through a right angle it will be parallel to the plane of the pencil and may be taken to coincide with it. In this position we get the circle used in chapter xx. We recommend the reader to go through the first pages of this chapter when reading the third and fourth.

To combine two wrenches on two screws, α and β, we have to construct the cylindroid containing the screws and the flat pencil spoken of. If on the two rays in this pencil which are the projections of α and β the intensities of the wrenches be set off (they are the forces which together with couples constitute the wrenches), then their resultant gives not only the intensity of the resultant wrench, but it lies on the ray which is the projection of the screw of the resultant wrench. From this follows at once: Any two wrenches on screws of a cylindroid combine to a wrench whose screw lies again on the cylindroid; and conversely, a wrench on a screw belonging to a cylindroid can be decomposed into two wrenches on any two given screws on the cylindroid. Also, on any three screws of a cylindroid wrenches can be determined which are in equilibrium. It need scarcely be stated that the ratios only of their intensities are determined; but it is of importance to remember this.

The above results for the composition of wrenches hold also for twists about screws, provided that their amplitudes are very small, in conformity with the well-known fact that small rotations are combined in the same manner as forces. For this reason Sir R. Ball has limited his investigations to cases where the twist velocities have infinitely small amplitudes. These include equilibrium, beginnings of motion due to impulses and small oscillations. He also supposes the forces always to have a potential. Within these limits his results are of absolute generality.

The remarkable analogy between forces and rotations which appears in analytical mechanics rather as an accidental, though interesting, circumstance, is raised in the theory of screws to a principle of paramount importance.

If a rigid body acted on by a wrench receives a small twist, then the work done by the wrench is the product of the intensity of the wrench, of the amplitude of the twist, and of a geometrical factor which depends solely upon the two screws of the wrench and twist. Half this factor Ball calls "*the virtual coefficient of the two screws.*" If the screws meet it is proportional to the cosine of the angle between them; if the pitches of both screws vanish, or more generally if their sum vanishes, it becomes the moment of the two lines on which the screws lie. It partakes, therefore, of the nature of both these quantities, and its analogies to the cosine especially are, in many cases, very marked. If the virtual coefficient vanishes, then no work is done by the wrench in consequence of the twist. Now the virtual coefficient of two screws, α and β, depends symmetrically on both, hence if a wrench on α does no work when the body is displaced by a twist about β, then also a wrench on β does no work during a twist on α. For this reason two screws whose virtual coefficient vanishes are called *reciprocal*.

An immediate consequence of the definition of reciprocal screws is this, that a screw which is reciprocal to two screws, α, β, is reciprocal to all screws on the cylindroid determined by α, β. For a twist about any screw, γ, on the cylindroid can be decomposed into two about α and β; but the wrench can do no work against these, and therefore it can do no work against a twist about γ.

It is also proved that through every point in space there pass a single infinite number of screws, which are reciprocal to a cylindroid. These lie on the generators of a cone of the second order. Similarly, all screws in a plane which possess the property in question envelop a conic, and in chapter xxi. it is shown that this is always a parabola.

Two screws which meet can be reciprocal only if they meet at right angles or if the sum of their pitches vanishes. This gives rise to one of the most powerful methods for finding reciprocal screws. Thus, as every line meets a cylindroid in three points, and therefore cuts three screws on it, and as the cylindroid contains only two screws of equal pitch, it follows a screw, α, reciprocal to a cylindroid must cut one screw on it at right angles, and the two others which it meets must have equal pitches, viz. these must be equal and opposite to the pitch of α; and from this, again, it is easily deduced that every line which meets one screw on a cylindroid at right angles cuts, besides, two others which have equal pitch; for if on this line a screw be taken with a pitch equal to one of the two remaining screws which it cuts, it will be reciprocal to the cylindroid.

Just as two wrenches on screws α and β always combine to a wrench on a screw lying on a certain cylindroid, so three wrenches on screws α, β, γ, which do not lie on a cylindroid, combine to a wrench on a fourth screw which is connected with the three given ones, and which depends on the two ratios only of the intensities of the three given wrenches.

The entirety of all the screws which are got by varying these ratios forms a system of a double infinite number of screws, which has been called a screw-complex of the third order.

If any four screws belonging to such a complex are selected, then a wrench on one of them can be decomposed into three wrenches on the others. It is also always possible to determine wrenches on the four screws which are in equilibrium, and the ratios of their intensities alone are then determined. Similarly, five independent screws, *i.e.* screws which do not belong to a complex of lower order, give rise to a complex of order five, and six independent screws to a complex of order six. To this latter complex all screws in space belong, for in chapter v. it is shown that in general any wrench can be decomposed into six wrenches on six arbitrarily selected screws. A screw-complex of order two is nothing but a cylindroid, and a complex of order one consists of one single screw. That a complex of order six exhausts all screws in space, says only that the number of all screws is ∞^5, if ∞^1 denotes the number of points in a line, or the number of values which a single real variable, x, may assume. That the number of all screws is ∞^5 is also at once evident if we consider that the number of lines in space is ∞^4, and that on each line we have a single infinite number of screws which are obtained by giving its pitch all possible values from $-\infty$ to $+\infty$.

There is an important theorem that the screws which are reciprocal to all screws in a complex of order n form themselves a complex of order $6-n$.

One of the chief uses made of these results consists in the introduction of screw co-ordinates, viz. six independent screws are selected as co-ordinate screws. Then the intensities of the components of a wrench on these six screws are taken as the co-ordinates of the wrench. In the same way the co-ordinates of a twist are obtained. Lastly, by the co-ordinates of a screw are understood the co-ordinates of a wrench of unit intensity on the screw, or those of a twist of unit amplitude about it. To get, then, the co-ordinates of any wrench on, or a twist about, a screw, the co-ordinates of the latter have only to be multiplied by the intensity of the wrench or the amplitude of the twist. Between these screw co-ordinates exists, however, an equation of the second degree, just as between the ordinary homogeneous point co-ordinates there exists a linear equation. A screw is thus completely determined by the ratios of its six co-ordinates, *i.e.* by five numbers, which again shows that

there are ∞^6 screws in existence. Having established the notion of these co-ordinates, there are next given, in chapter v., expressions in terms of the co-ordinates for the resultant of a number of wrenches or twists, for the work done by a wrench on one screw during a twist on another, and so on. These expressions are much simplified by selecting the screws of reference in a particular manner, viz. so that any two of them are reciprocal, and such a system of "co-reciprocal" screws is afterwards always used.

The expression for the virtual coefficient of two screws is in general a lineo-linear function of the co-ordinates of both screws. But this is simplified for the special system of co-ordinate screws just mentioned, in reducing to an expression of six terms only, each being the product of the co-ordinates of the two screws relating to the same co-ordinate screw into the parameter of this screw. This expression must vanish if the two screws shall be reciprocal. Hence the condition that a screw shall be reciprocal to a given screw is expressed as a linear equation between its co-ordinates, and it is important to add that every linear equation between its co-ordinates can be interpreted as meaning that the screw is reciprocal to some other screw. But one linear equation enables us to express one of the co-ordinates in terms of the others, so that all the co-ordinates of all screws which are reciprocal to a given screw can be expressed in terms of five co-ordinates, in other words, a screw in a complex of order five is determined by five co-ordinates. In the same way two linear equations limit a screw to a complex of order four, and so on, till we come to five equations as determining one single screw; which also shows that there is always one screw which is reciprocal to five given screws.

We leave for the moment the line followed by Ball and Gravelius, in order to indulge in some very general speculations, in close connection with chapter xix., which seem best suited to give, in as short a compass as possible, a clear insight into the nature of the whole system of screws.

We are accustomed to express the fact that the number of points in a plane is ∞^2 by saying a plane, or in fact any surface, is of two dimensions if we consider the points as elements. Space is, in the same sense, of three dimensions, whilst it is of four dimensions if we consider the lines as elements.

We may extend this language, and say the aggregate of all screws forms a space of five dimensions, or as Clifford would have said, it is a five-way spread. If we now assume between the co-ordinates one equation, we may speak of the locus of screws whose co-ordinates satisfy this equation. It will be a four-way spread, or a space of four dimensions. This locus is called by Ball a screw-complex of order five and degree m, if m is the degree of the equation. The complexes spoken of before are of the first degree.

The geometrical theory of screws becomes thus identical with the geometry of a space of five dimensions, which latter we may call the screw-space.

Let us consider now two such complexes of 1st degree, one of order m, the other of order n. The first is determined by a set of $6 - m$ linear equations between the co-ordinates, the second by $6 - n$ such equations. All screws common to both have therefore to satisfy $12 - m - n$ equations, and in case that this number is not greater than six, they will constitute a complex of order $6 - (12 - m - n) = m + n - 6$. Thus a complex of order 4 and a complex of order 5 will have a complex of order 3 in common, whilst two complexes of order 3 will in general have no screw in common, though they may have a single screw or a whole cylindroid in common.

The geometrical theory of screws as the geometry of a particular space of five dimensions is not a mere extension of the ordinary Euclidian geometry. The six homogeneous co-ordinates of a screw are, as has already been mentioned, connected by an equation. This is of the form $R = 1$, where R is a quadratic expression of the co-ordinates. All elements at infinity in our screw-space are given by the equation $1 = 0$ or by $R = 0$. The *absolute* is thus a quadric locus, and therefore we have to deal with non-Euclidian geometry.

The advantage to the theory of screws to be derived from a study of this geometry are apparent at every step. We may in our screw-space conceive curves and surfaces of from 1 to 4 dimensions, by taking one or more equations between the co-ordinates. Of these, equations of the first degree determine the screw-complexes. But equations of the second degree, which determine quadric complexes, or as Ball calls them screw-complexes of second degree, are also constantly of use. Such an equation may be taken in a complex of order n. In the treatise before us they appear in congruences of the 3rd and 6th order. We will give here one illustration.

Let $p_1, p_2, \ldots p_n$ be the pitches of the n co-reciprocal co-ordinate screws, and let $a_1, a_2, \ldots a_n$ be the co-ordinates of a screw a with pitch p_a. Then is p_a given by the equation

$$p_a = p_1 a_1^2 + p_2 a_2^2 + \ldots + p_n a_n^2.$$

This equation can be made homogeneous by aid of $R = 1$, and becomes

$$Rp_a = p_1 a_1^2 + p_2 a_2^2 + \ldots + p_n a_n^2,$$

where R also is supposed to contain n of the a only, the others being replaced by aid of the linear equations which determine the complex of order n. It follows that the absolute $R = 0$ is the locus of screws of infinite pitch, whilst

$$p_1 a_1^2 + p_2 a_2^2 + \ldots + p_n a_n^2 = 0$$

is the locus of screws of zero-pitch. Both are quadrics.

If we take a screw β, we may form its polar with regard to any quadric. If we select the last quadric mentioned, the polar is

$$p_1 a_1 \beta_1 + p_2 a_2 \beta_2 + \ldots + p_n a_n \beta_n = 0.$$

But this equation is also the condition that a and β are reciprocal screws. In each complex the quadric of zero-pitch becomes thus of special importance, reciprocal screws being conjugate poles with regard to them.

As we cannot directly realize a space of more than three dimensions, it becomes of importance to represent the elements in such a space by other elements in ordinary space, and, when possible, by elements in a plane. That this is always possible is clear.

For instance, as all conics in a plane are ∞^5 in number, we have as many conics in a plane as there are screws in space, and we may therefore represent each screw by a conic in a plane. To screws on a cylindroid would then correspond all conics in a pencil. We might then speak of the cross-ratio of four screws as given by the cross-ratio of the corresponding conics in the pencil. All screws belonging to a complex of order 3 would be represented by conics forming a net, *i.e.* by conics having a common polar triangle.

We thus get a graphical representation in a plane, and can obtain our results by constructions in a plane. But the geometry of conics in a plane has scarcely been far enough developed to make general use of them, and for screw-complexes of lower order simpler representations may be found. Thus the screws on a cylindroid can be represented most conveniently by the points on a circle which stands in close relation to the cylindroid and gives rise to a graphical solution of problems relating to a body with two degrees of freedom. This is done in chapter xx., full of interesting detail. Again, screws in a complex of order 3, whose number is ∞^2, can be represented by

points in a plane. This has been worked out in chapters xxi. and xxii. In fact, here the screw co-ordinates, three in number, are simply taken as tri-linear co-ordinates of a point. It follows at once that the locus of points with equal pitch must be a conic, the "absolute" being the locus of pitch ∞, and one conic relates to zero-pitch. This latter may, without loss of generality, be made a circle.

It is of interest to notice that for a screw-complex of order 3 the screws which have a given pitch form themselves a quadric surface, viz. they form one set of generators on a hyperboloid, the other set of generators having pitch $-p$, and containing thus screws in the complex reciprocal to the others.

Other quadrics enter the theory, especially one containing the locus of screws about which a body may twist without receiving kinetic energy, and which is, of course, imaginary; and one connected with the potential. These last two determine the principal screws of inertia, of which more later on.

For screw-complexes of order 4 no graphical representation is given. The difficulty lies here in this—that the dynamics require constantly metrical relations, and these are not very simple in the plane representation, by conics for instance. It is here that the non-Euclidian character of the geometry comes out.

These speculations are in close connection with the contents of chapter xix., where projective relations between two congruences of the same order are investigated. It is here that Herr Gravelius has more particularly introduced original work of his own in bringing Sir R. Ball's Mr. One-to-one more prominently to the foreground.

Up to this we have considered chiefly the geometry of systems of screws. It is now time to consider the kinematics of a rigid body and the action of forces on it.

If a body is perfectly free it can twist about every screw in space. As these can be decomposed into six twists about the co-ordinate screws, the body is said to have six degrees of freedom. If the body is constrained in any manner—and here the generality of the nature of the constraint has to be noticed—then it will not be able any longer to twist about all screws. But we have seen already if it can twist about n screws it can twist about all screws belonging to the complex of order n derived from them. The freedom of a body is therefore fully characterized by the complex which contains all screws about which the body can twist. If this is of order n, then the body has n degrees of freedom. An attempt to twist the body about any other screw will evoke a reaction due to the constraint which will reduce to a wrench upon some screw. Such a wrench cannot do any work against a possible twist of the body, hence the screws on which wrenches of constraint are possible must be reciprocal to the screws which determine the freedom of the body; they form, therefore, the reciprocal complex. We thus get the very general theorem about the equilibrium of a body. If a body has n degrees of freedom then it will be in equilibrium under the action of all wrenches on screws of a certain complex of order $6 - n$. This complex may be called the complex of constraint.

Again, if a body is subjected to an impulsive wrench upon a screw, η, not belonging to the complex of constraint, it will begin to turn about some screw, α, called the instantaneous screw. At the same time an impulsive wrench of constraint will be evoked. Conversely, in order to produce a twist on α as instantaneous screw we may apply an impulsive wrench on η, but with this we may combine a wrench on any one of the screws belonging to the complex of constraint. As the latter is of order $6 - n$, all screws derivable from these, together with the screw η will form a complex of order $7 - n$ This complex of order $7 - n$ and the complex of order n which determine the freedom have $7 - n + n - 6 = 1$ screw in common (see above). This screw is called the reduced impulsive wrench.

We thus have proved if a body has freedom of order n, then there is always one and only one screw, η, in the complex which determines the freedom, such that an impulsive wrench on it makes any given screw, α, the instantaneous screw. The converse, also, is evidently true. Between the impulsive and instantaneous screw in the complex exists, therefore, a one-one correspondence, or, to express this differently, the complex of instantaneous and that of impulsive screws are projective. They are also coincident. But if we have two coincident projective spaces of $n - 1$ dimensions, then there are always n screws in one which coincide with their correspondents. This proves if a body has n degrees of freedom, then there exist n screws, and in general only n, such that an impulsive wrench on one of them produces a twist on the same screw. These n screws—and the discovery is one of the triumphs of the theory—are called the principal screws of inertia, as they depend on the distribution of matter in the body. These screws are also co-reciprocal, and may therefore be taken as co-ordinate screws. They are a generalization of the principal axes of inertia in the ordinary theory; and to show their importance it is sufficient to point to the importance of the principal axes of inertia in the ordinary theory of a free body, or of a body of which one point is fixed, and to remember the simplification obtained by taking them as axes of reference.

For a free body the screws of inertia lie on the principal axes of the body which pass through the mass-centre, two on each, with pitches equal to the corresponding radius of gyration, taken positive for the one and negative for the other. The ordinary theory has no analogon to this if the body is constrained, excepting in the few cases where a point or an axis of the body is fixed, or where the body has plane motion only.

It is in such generalizations that the theory of screws excels. It has given us here the best and simplest co-ordinates for all cases of the motion of a single rigid body acted on by any forces and constrained in any manner conceivable.

We will now suppose that the co-ordinates thus pointed out are used, and find the instantaneous screw corresponding to any given impulsive wrench. Each component wrench produces a twist about its own screw, whose amplitude depends in a very simple manner on the intensity of the impulsive wrench; so that the intensities of the component twists are known, and these give the resultant twist.

We next consider the kinetic energy, T, of the body due to a twist on a screw, α. Let α_1, α_2, . . . be its components, p_1, p_2, . . . the pitches of the co-ordinate screws, and $\dot{\alpha}$ the twist velocity. It is then shown that, M being he mass of the body,

$$T = M\dot{\alpha}^2(p_1{}^2\alpha_1{}^2 + p_2{}^2\alpha_2{}^2 + \ . \ . \ . \ + p_n{}^2\alpha_n{}^2).$$

Denoting the expression in the brackets by $u_\alpha{}^2$, we have $T = M\dot{\alpha}^2 u_\alpha{}^2$. The quantity u_α is a length; the expression for T is therefore of the same form as that for the rotation of a body about an axis with angular velocity $\dot{\alpha}$, the radius of gyration being replaced by $u_\alpha/\sqrt{2}$. This last expression deserves a name. If we adopt Clifford's word "spin-radius," instead of radius of gyration, the name twist-radius suggests itself as suitable for u_α or $u_\alpha/\sqrt{2}$.

We now come to consider the problem of small oscillations. Let there then be a body of n degrees of freedom n a position of equilibrium under a system of forces which have a potential V. Let A denote the complex defining the freedom. If the body be displaced by a small twist about a screw, α, belonging to the complex A, then the forces are not any longer in equilibrium; hence they will give rise to a wrench on some screw λ. This wrench may be combined with any wrench of constraint; but just as in case of impulsive wrenches there is one single screw

λ belonging to the complex A, hence now also we have in the complex A a one-one correspondence between the screws a and the screws λ. There are therefore, again, n screws a, which coincide with their corresponding screws λ. These have got the name of "principal screws of potential." They depend on the system of forces or on the potential V, just as the screws of inertia depend on the distribution of matter. These n screws, again, are co-reciprocal. They have the property that a twist about one of them evokes a wrench on the same screw, the wrench being due to the applied forces. To show the importance of these principal screws of potential it will be sufficient to remark that the potential is, under the circumstance explained, a homogeneous function of the second degree of the n co-ordinates by which the displacement is defined. This function becomes the sum of n terms containing the squares only of the co-ordinates if the principal screws of potential are taken as co-ordinate screws.

Now, suppose that the body has been displaced by a twist about a screw a, this could be done by a wrench upon the screw η, which as impulsive screw corresponds to a as instantaneous screw. At the same time this displacement calls a wrench on a screw λ into play due to the potential V. To every screw a corresponds thus one screw η and one screw λ. Hence the latter are also connected by a one-one correspondence, and there are therefore n screws a such that the corresponding screws η and λ coincide. The screws a thus obtained are called "harmonic screws." They possess this property: A twist about a harmonic screw evokes a wrench which in its turn tends to produce a twist on the original harmonic screw. Hence if the equilibrium is stable this wrench will tend to twist the body back to the position of equilibrium, and thus produce small oscillations about the harmonic screw. From this we get the following theorem, distinguished again by its great generality:—

If a rigid body having n degrees of freedom is in a position of stable equilibrium under the action of a system of conservative forces, then it can, on being disturbed, perform n distinct oscillations, which consist each of a twisting about a single screw. Every other oscillation is a combination of these.

These are the chief results which so far have been obtained by the theory of screws as applied to a single rigid body. They form the contents of chapters vi. to xii. These general results are, in the next six chapters, applied and considered more in detail for each of the six possible cases of degrees of freedom which a rigid body may have. Then there follow four chapters on graphical methods, already referred to.

All the former investigations relate to one single rigid body. But Sir R. Ball, in 1881, published a paper in which he extends his theory to systems of rigid bodies by a method as beautiful as it is suitable to the purpose.

The bodies, of which we suppose there are μ, are taken in a definite order. Every body of the system will at every moment twist about some screw. We thus get a et of μ screws, about which at any moment the bodies twist. If we take two consecutive twists, then their resultant depends only on the ratios of the two amplitudes, and conversely the screw of the resultant determines this ratio. If the screws about which two consecutive bodies twist are given, and also the screw on which their resultant lies, then the amplitude of the first twist determines that of the other. If, therefore, the screws about which the μ bodies twist at any moment are given, and besides the $\mu - 1$ screws on which the resultant twists of consecutive bodies lie, then the amplitude of the first determines that of every other twist. The set of $2\mu - 1$ screws thus obtained is called a screw-chain, and it is said that the system of bodies twists at any moment about a certain screw-chain.

In case of systems of rigid bodies, the screw-chain has to be considered as the fundamental entity, which takes the place of a screw in case of a single body.

In a finite number of bodies we get a screw-chain of a finite number of screws. These will, in the screw-space of five dimensions, be represented by a finite group of points (elements). If, however, the number of bodies increases and becomes infinite, as in the case of the molecules of a fluid, this group of points may form a continuous locus of one or more dimensions. We may thus get, instead of screw-chains, continuous curves and surfaces of screws, and their geometry will be that of a group of points in five-dimensional non-Euclidian space.

This suggests an enormous field for investigation, and it is of interest to see that every progress in the algebra and geometry of such a space must indicate also progress in dynamics.

But these are speculations far beyond the contents of the book under review.

All results obtained for twists can at once be transferred to wrenches. Accordingly a system of forces acting on a system of bodies can be reduced to a wrench upon a screw-chain.

There are reciprocal screw-chains, screw-chains of inertia, complexes of screw-chains, complexes of freedom and of constraint, and complexes reciprocal to them. In fact, the screw-chain seems now to take in every respect the place of the screw in the theory of a single body. These screw-chains in their kinematical and dynamical applications to systems of rigid bodies form the contents of the chapters xxiii. and xxiv.

The last two chapters in the book give Sir R. Ball's theory of content, in which the author tries successfu to overcome the difficulty which offers itself in the determination of metrical relations without any reference to measuring a length. By "content" is understood the aggregate of all elements in what Clifford called a three-way spread. The investigation is carried on quite algebraically by aid of the methods of Grassmann's "Ausdehnungslehre." In the book before us this is worked out, partly with reference to Clifford's theory of biquaternions, and ends with the introduction of Clifford's vectors in non-Euclidian space.

It will be asked what progress in the science of dynamics, and through dynamics in natural philosophy, has been made by Ball's creation. The theory of screws is a mathematical speculation full of life, full of interest and charm for the mathematician who likes to find new physical interpretations for geometrical and algebraical results and methods. The physicist, however, may say that the theory does not increase our power over Nature. But I am inclined to think that when further developed it will be a great, perhaps a very great, help to progress. Does not every molecule of a fluid having rotational motion twist about some screw? And does not a vortex-line suggest a screw-chain containing an infinite number of elements?

The theory of screw-chains, containing a finite number of elements belonging to a system of bodies with one degree of freedom, seems to indicate a truly scientific classification of mechanisms, and may conceivably render great aid in the invention of mechanisms which answer a given purpose.

The essentially geometrical character of the new method seems particularly well adapted to give graphical solutions of dynamical problems, and thus a "graphical dynamics" appears to find here a sound foundation. In this direction much has been done already, but much remains to be done. Also the restrictions of infinitely small amplitudes of the twists has to be broken through, and the infinitesimal calculus has to be pressed into the service.

Meanwhile, we congratulate Sir Robert Ball on the results which his persevering labours have achieved, and Herr Gravelius on the courage which led him to under-

take the task of writing a text-book on this subject, and on the success with which he has accomplished it. The book ought to give a great impulse to the study of this theory, and to enlist many friends in its service.

O. HENRICI.

THE SIXTH SCIENTIFIC CRUISE OF THE STEAMER "HYÆNA" WITH THE LIVERPOOL MARINE BIOLOGY COMMITTEE.

THE Liverpool Salvage Association having kindly placed their s.s. *Hyæna* once more at the disposal of the Liverpool Marine Biology Committee, a four-days' dredging cruise was arranged and successfully carried out at Whitsuntide. The old gunboat left the Mersey on Friday, May 23, and steamed to the Menai Straits. Some of the party spent the afternoon and evening collecting on the shore at Puffin Island, off which the *Hyæna* was anchored for the night. On the following morning, after a few hauls of the dredge near Puffin Island, and between Penmon Point and Beaumaris, and again off Port Dinorwic, the steamer went through the straits to Carnarvon Bay, and commenced working along the southern coast of Anglesey.

The dredges and various kinds of tow-nets, surface and bottom, were used at intervals. Mr. W. E. Hoyle's deep-water closing net, which has now been modified so that its movements of opening and closing are effected by the passage of an electric current, was experimented with frequently during the cruise—not so much with the object of collecting specimens, as for the purpose of detecting and remedying any possible defects in the construction, and of guarding against conditions which might interfere with the proper action of the apparatus. On the whole the net worked satisfactorily, the causes of occasional failures were discovered, and when the improved form of frame used by the Germans has been adopted, the apparatus will no doubt be a most useful addition to the implements of the marine biologist.

The *Hyæna* anchored for the night in a small rocky bay, Porth Dafarth, on the south side of Holyhead Island, Anglesey, and half the party of over twenty biologists were landed to sleep on shore. After dark those who remained on board commenced tow-netting by electric light, and repeated with some modifications the experiments which had been made during the last two cruises of the *Hyæna* at the Isle of Man (NATURE, vol. xxxviii. p. 130, and vol. xl. p. 47) in 1888 and 1889. The large arc lamp was hoisted over the side of the ship so as to throw a strong glare on the water, and Edison-Swan incandescent lamps were sent down to the bottom in tow-nets which were hauled up at intervals. Comparatively few Cumacea, Amphipoda, and Schizopoda were obtained this time, but shrimps and young fishes were—for the first time in our experience—attracted by the light to the surface, and some of them were caught and preserved. One of the ship's boats was kept in the area illuminated by the arc lamp, and by leaning over her side the small objects in the surface-layer of water could be most distinctly seen, and particular animals picked out and captured with a hand-net as they darted about in the neighbourhood of the light.

Two of the party got up at 3 a.m., and took a surface tow-netting about dawn, which was afterwards found to contain a much greater number of Copepoda, and more variety, than any of the other tow-nettings, either day or electric light, surface or bottom. Amongst other interesting things it contained a large number of *Peltidium depressum*, which had not been taken at all during the day, and only in very small numbers with the electric light bottom net. This same species has recently been taken in quantity at Puffin Island by leaving a tow-net out all night attached to a buoy. It is usually found sticking on *Laminaria* in the day-time, but evidently comes to the surface in abundance late at night or early in the morning.

The following day was spent in steaming slowly about off the southern coast of Anglesey, dredging and tow-netting at frequent intervals. The surface life was found to be very poor—comparatively few Copepoda and almost no representatives of other free-swimming groups being obtained; but Mr. Thompson noticed the relative abundance in all the tow-nettings, both surface and bottom, during the day, and also with the electric light, and at dawn, of unusually large specimens of *Dias longiremis*, and also the prevalence of the somewhat uncommon *Isias clavipes* in all the surface gatherings, though none were taken in the bottom ones.

The dredging results were fairly good: some very fine sponges were obtained, and Ascidians were plentiful. One patch of rich ground was discovered near Rhoscolyn Beacon, where *Comatula* was brought up in abundance along with various Tunicata, Holothurians, Nudibranchs, Zoophytes, Polyzoa, and large sponges. After dark, in Porth Dafarth, the electric lights were again used for a couple of hours. This time the large arc lamp was taken to the stern and suspended close to the surface of the water, but as it was not working steadily one of the incandescent submarine lamps was lowered over the side and kept a few inches under water, and this proved most effective in attracting animals to a stationary tow-net or a hand-net beside it. On the fourth day the *Hyæna* returned through the Menai Straits to Liverpool. As usual the specimens collected have been distributed to specialists, and the detailed reports upon the various groups will appear in the next volume of the "Fauna of the Liverpool District."

W. A. HERDMAN.

W. S. DALLAS.

THE death of this genial and accomplished man will awaken feelings of no ordinary regret, not only among geologists, but among naturalists all over the country. For two-and-twenty years his tall, handsome person has been the most familiar figure at the rooms of the Geological Society in Burlington House. Always at his post, with a pleasant smile of welcome, ever ready with assistance from his large treasures of knowledge and experience, knowing more intimately than anyone else the affairs and traditions of the Society, proud of its history and keenly sensitive for its scientific reputation, he had come to be looked upon as a kind of *genius loci*—the living embodiment of the Society's aims and work.

Of those who knew Mr. Dallas only in his later years, and saw his whole-hearted devotion to the geological labours intrusted to him, probably few were aware that he was not always a geologist. He began life with zoological inquiries, and devoted his attention more especially to insects. His early papers appeared in the Transactions of the Entomological Society, but he prepared also a Catalogue of the Hemipterous Insects in the British Museum, which was published as far back as the years 1851–52. Yet he did not confine himself to one branch of zoology; on the contrary, his reading and knowledge ranged over a wide domain in natural history. In the year 1856 he published his "Natural History of the Animal Kingdom," by far the best work of the kind in its day, which rendered important service to biology, in making the study of living forms more attractive, and in providing for that study a much more accurate groundwork than had ever before been obtainable. The value of his labours was recognized not long afterwards by his being appointed Curator of the Yorkshire Philosophical Society's Museum at York—an office which he held for ten years, until in 1868 he obtained the post which he held up to the last—that of Assistant Secretary, Librarian, and Curator to the Geological Society of London.

After his return to reside in London he found the duties of the office he had undertaken so engrossing, and the cares of domestic life so exacting, as to leave him little or no spare time for original inquiry. He devoted such leisure as he could command to translating, editing, and other scientific labour of a literary kind. Biologists will especially remember the appearance of his translation of Fritz Müller's "Facts and Arguments for Darwin," shortly after the beginning of the controversy aroused by "The Origin of Species." His wide range of knowledge in natural science, and his literary tact and experience, made him an unrivalled editor of a scientific periodical. The volumes of *The Quarterly Journal of the Geological Society* for the last twenty years will remain as a memorial of the accuracy, skill, and punctuality of his work. It will be difficult to find another assistant secretary so deft and helpful as he: it will be, however, still harder to discover one who to ample scientific acquirements and long experience will unite a nature so gentle and kindly as his, and a character so honourable and sincere. Mr. Dallas may be said to have died in harness. Though for some time he had been growing gradually feebler, he attended the evening meeting of the Geological Society only a fortnight ago. But the hand of death was then visibly upon him. Two days afterwards he was struck down with paralysis, and, after lingering a week, died on the morning of May 28, at the age of sixty-six. Last Monday his associates of the Geological Society laid him in his grave in the Norwood Cemetery. A. G.

NOTES.

BESIDES the death of Mr. W. S. Dallas, the Assistant-Secretary of the Geological Society, the ranks of the geologists of this country were further thinned last week by the loss of another well-known and most esteemed student of geology—Mr. John Gunn, of Norwich. Though not distinguished as a writer on geological subjects, he has long been looked up to as the chief authority on that most interesting deposit—the Cromer Forest-bed; and as the most indefatigable and successful collector of its organic contents. He had, moreover, an extensive knowledge of all the geological formations of East Anglia. He was, likewise, fond of antiquarian researches, and in early life did good service among the archæological and ecclesiastical antiquities of his county. But while always eagerly seeking fresh information and gathering a vast store of facts in many departments of inquiry, he refrained from rushing frequently into print, while on the other hand, with generous self-abnegation, he was ever ready to place his materials at the service of science and the public. Every honest inquirer was always welcome to any information or assistance he could give. After amassing a magnificent suite of fossils, illustrating especially the mammalian life of Pliocene time in England, he presented it to the Norfolk and Norwich Museum, where it forms one of the most attractive and instructive features of the collection, and fills what is called after him the "Gunn Room." Mr. Gunn had reached his eighty-ninth year.

WE are glad to gather from the statement made in the House of Commons on May 22 by Sir John Gorst, in reply to a question from Sir Henry Roscoe, that the new regulations which will shortly be issued by the Civil Service Commission for the competitions for admission to the higher branch of the Indian Civil Service are, in the opinion of Sir John Gorst, likely to satisfy the desire which is widely felt at the Universities and elsewhere that they "shall secure more equal prospects of success for those whose chief studies have been in science than are at present accorded in these competitions." Those who are interested in this important educational question will be glad that Sir Henry Roscoe has directed the attention of the authorities at the India Office to this matter, and they will hope that if the new regulations are not found to satisfy the necessities of the case, he will continue his exertions. We do not wish to be prophets of evil, but experience unfortunately shows that the Civil Service Commissioners are by no means likely to put science subjects on anything like a fairly equal footing with classics except under considerable pressure from public opinion. It will therefore be important that prompt combined action shall be taken in support of Sir Henry Roscoe by those who have interested themselves in the question, if the new regulations do not prove to be of a satisfactory character. If the present opportunity of securing that the conditions of admission to this important service be put on a proper footing be lost, it may be long before another occurs. Such action has, however, succeeded in other cases, and ought to do so in this case also.

IN moving the Education Estimates on Tuesday evening, Sir W. Hart Dyke gave an elaborate and most careful account of the new Code, the leading provisions of which we have already discussed. Among the speakers who took part in the subsequent debate or conversation was Sir Henry Roscoe, who congratulated the Vice-President on having for the first time carried out some of the recommendations of the Royal Commission on which he had had the honour to serve. He welcomed the proposal to give a grant for manual instruction. He was also pleased to learn that the Vice-President took to heart one of the recommendations which laid the foundation for technical instruction—a foundation which many of them for a long time had hoped would be laid. It was gratifying to learn that already great progress had been made in several of the larger towns with regard to technical instruction. He hoped that the question of drawing would progress. He thought the specialization of science ought not to be made before the fourth standard. The question of training teachers was one which referred to probably the most important portion of the Code. He welcomed all that it was proposed to do. He believed that the new Code would mark an era in the educational progress of the country. Mr. Mundella, in the course of a short speech, said he had risen only to express his thanks to the Vice-President of the Council for the liberal provisions of his Code. He regretted, however, that these provisions had not been somewhat extended. Why had the Vice-President not gone somewhat further with respect to the recommendations of the Royal Commission as to raising the standard of age, and extending the school life of the child? They might make the best and most liberal arrangements for education, but if the child's school life was to end at ten years of age, they were wasting their money. In large towns there were thousands of children who went to full-time labour after the fourth standard. In many rural districts, especially in the west, the second standard was the half-time standard, and two years ago that had been the case in Bradford. Why could not the right hon. gentleman screw up his courage and adopt the recommendation of the Royal Commission, and do for England what was done in Scotland? They should have a minimum standard for half-time. He hoped that later on the right hon. gentleman would be able to announce that he had made some provision for meeting the suggestions which had been offered with regard to raising the age at which the school life of the child should end, and raising the full and half-time standards.

A DEPUTY Linacre Professor of Human and Comparative Anatomy is to be appointed at Oxford. He will hold office during the continuance of Prof. Moseley's illness. Candidates must send in their applications on or before June 21.

GOOD progress has been made with the arrangements for the fifty-eighth annual meeting of the British Medical Association, under the presidency of Dr. W. F. Wade, senior physician to

the Birmingham General Hospital, to be held in Birmingham on July 29, 30, and 31, and August 1 next. There will be three addresses—an address in medicine, by Sir W. Foster, M.D., M.P., of Birmingham; an address in surgery, by Mr. Lawson Tait, of Birmingham; and an address in therapeutics, by Dr. William Henry Broadbent, of London. The scientific part of the meeting will be carried on in twelve sections. It is now fifty-six years since the Association first held its meeting at Birmingham.

AT a meeting of the London Committee of the Edinburgh Exhibition on Tuesday, Mr. S. Lee Bapty, the general manager of the Exhibition, said the visitors during the first month had numbered 470,000. This was largely in excess of his most sanguine anticipations, and was all the more remarkable considering the state of the weather during most of the month. If the same number of visitors continued each month till October, there would be a total of over four millions. A very important exhibit of electrical appliances from forty manufacturers in France had just arrived, and these would be on view at the time of the approaching visit of the Lord Mayor and Sheriffs of London to Edinburgh.

AT the meeting of the Society of Arts on May 15, Mr. C. Washington Eves read a valuable paper on Jamaica and its forthcoming Exhibition. Apparently there is good hope that the Exhibition will be a decided success. The exhibits will be divided into six groups—raw materials; implements for obtaining raw materials; machines and processes used in preparing and making up the raw materials into finished products; manufactured goods; educational appliances; fine arts, literature, and science. The section devoted to science will include maps and charts of the West Indies, and objects relating to engineering, sanitation, gas, electricity, astronomy, and anthropology. After the reading of the paper there was a discussion, in the course of which Mr. Morris, of Kew, said there was every indication that makers of machinery and others would send out appliances, and there was but little doubt that immense good would result to the island from the Exhibition.

THE last Friday evening discourse at the Royal Institution will be given on June 13, by Prof. Silvanus P. Thompson. The subject will be "The Physical Foundation of Music."

THE authorities of Wadham College, Oxford, announce that in the election to one of several exhibitions which are open to competition preference will be given to any candidate who shall undertake to read for honours in natural science from the time of his admission into College, and to proceed to a degree in medicine in the University of Oxford.

THE *American Naturalist* states that the Marine Biological Laboratory at Boston, U.S.A., has issued a satisfactory annual report. The laboratory was crowded last summer, and the trustees appeal for donations to the amount of 7000 dollars for additions to the building, an increase in the library, and a steam-launch.

THE Botanical Society of Regensburg—one of the oldest societies of the kind in Germany—celebrated its hundredth anniversary on May 15.

THE late Herr M. Winkler, of Görlitz, has bequeathed his fine herbarium, comprising 150,000 specimens, and his botanical library, to the Botanical Garden at Breslau.

THE members of the German and Austrian Alpine Club have elected a scientific committee, consisting of Prof. Penik, Vienna, Dr. Finsterwalder, Munich, Councillor Hann, Vienna, Prof. Partsch, Breslau, and Prof. Richter, Graz. This committee will investigate scientific questions relating to the Alps, devoting especial attention to glaciers and mountain streams. The results will be made known in the official publications of the Club.

THE new Zoological Garden and Park at Rock Creek, Washington, to which we referred the other day, will be under the direction of Mr. W. T. Hornaday. It is stated that Prof. Frank Baker will be prosector, and will have charge of the department of comparative anatomy in the United States National Museum.

TELEGRAMS received at New York on June 3 stated that shocks of earthquake had been felt at Lima on the previous morning. The earthquake was one of the severest that had been experienced there for years. There were three distinct shocks.

WE learn from *Science* that the *Princess Louise*, which arrived at Victoria, B.C., from Skidegate and way ports, on the evening of April 24, brought news that on February 24 an earthquake shock was felt on all the islands around Skidegate, especially on the west coast of Queen Charlotte Islands, where a few old shanties were levelled to the ground. The totem-poles of the Indians shook like leaves, and in some places the earth was cracked. The shock lasted for about thirty seconds, during which time the Indians were wild with fright. A number of them ran to the church and crowded in. Since that time there have been about twenty different shocks, the last one being on April 12, although none was nearly so severe as the first. A very slight shock was felt at Skeena.

DR. DAVID P. TODD, writing to the *Nation* from the U.S.S. *Pensacola*, at Ascension, on March 16, refers in terms of high appreciation to the work done in meteorology by his colleague Prof. Abbe. A "nephoscope" was specially constructed for the Expedition on board the *Pensacola*. Prof. Abbe has elaborated a method for the use of this instrument in determining the actual height and velocity of clouds by combining observations made when the vessel or observer moves successively in two different directions, or with two different velocities; and he calls this the "aberration method," to distinguish it from ordinary parallax methods. His main work has been a determination of the motions of the atmosphere from a study of the lowest winds and the successive strata of clouds; and, to this end, he has maintained daily observations with the nephoscope at sea, and when possible on shore. The visible clouds, he concludes, give little or no information as to the motions of the atmosphere in the widest sense, but prove that the atmosphere is everywhere divided into local systems of currents, so that we have winds circling around a storm-centre, a high barometer, an ocean, or a continent; and, at least in the Atlantic, have no winds that circulate exactly as they would do on a rotating, uniform, smooth globe. The angles of inflow and outflow have been determined for three or four successive strata of air in mid-Atlantic; also the relations of the cloud-appearances to distant storms, squalls rains, and changes of wind, with such accuracy that on many occasions predictions of such phenomena have been made and verified.

MR. S. H. C. HUTCHINSON, Meteorological Reporter for Western India, has written an excellent "Brief Sketch of the Meteorology of the Bombay Presidency in 1888-89." The meteorology of that year was characterized, Mr. Hutchinson says, by strongly marked deviations from the weather conditions of an average year. Of these, the most noteworthy were, a general rise of abnormal barometric pressure for a considerable period, a general deficiency of rainfall in September, and the scanty rainfall throughout the year. Mr. Hutchinson points out that all these variations are of much practical importance, and, from a scientific point of view, of considerable interest, inasmuch as they confirm the laws or principles deduced from the meteorological data of many past years. These laws or principles are, that the rainfall is deficient when barometric pressure is above

the normal height, and excessive when the barometric pressure is lower than usual; that at or about the epochs of minimum solar spotted area, high abnormal barometric pressure movements make their appearance, and that at or about the epochs of maximum solar spotted area, abnormally low pressure movements take place in India and over greater part of the tropics; that cyclones are formed in the trough of a relatively minimum barometric pressure; and lastly, that the number of atmospheric disturbances is great at the epoch of minimum sunspots.

IN Dr. A. Petermann's *Mitteilungen* (Heft v., 1890), Dr. A. Supan gives some particulars respecting Emin Pasha's meteorological journal, which will shortly be published. The registers extend from August 1, 1881, to February 27, 1890, and, omitting the interruptions, contain observations for seven years and ten months. They are said to have been taken with great care, and may be divided into three periods: August 1, 1881, to April 24, 1885, at Ladó; July 13, 1885, to December 5, 1888, at Wadelai; and March 1 to December 4, 1889, during the march with Stanley to the coast. On the latter date Emin Pasha met with his serious accident, but so great was his desire to continue the observations, that he resumed them on January 5, 1890, in the German hospital at Bagamoyo. Dr. Supan regrets the non-publication of Mackay's observations at Rubaga (Uganda), which were sent to the Royal Geographical Society in 1886, as they promise to be the most important contribution to the climatology of the interior of tropical Africa.

A CHEAP bunsen burner is being sold by Messrs. John J. Griffin and Sons, which possesses many advantages over the ordinary burner, with central gas jet constructed so that the gas and the air may be simultaneously regulated. In the new patent burner the gas passes into the tube through a way cut in the side of the tube, which is therefore open from top to bottom. Such an arrangement is a considerable improvement, inasmuch as there is no jet to become choked. The burner can also be easily taken apart in order to clean the tube when corroded. To regulate the flow of gas under varying gas pressures small movable disks are provided, which, however, are little better for the purpose than the older method of rotating a cylinder concentric with that containing the air-inlets. Combinations are also made in which each burner can be regulated or extinguished separately, thus rendering them very suitable for combustion furnaces.

AN elaborate Report on the Natal forests, by Mr. H. G. Fourcade, has just been issued. He arrives at the following conclusions:—(1) The Natal forests, more particularly the timber forests, are well worth preserving, whether from an economic or climatic point of view, and the Government alone is competent to undertake the work. (2) The condition of the forests is, for the most part, lamentable, and the result of past abuses; their destruction is proceeding apace, and the following measures are recommended to insure their preservation and utilization to the best advantage: (*a*) The survey and demarkation of the principal forests. (*b*) Their protection from fires, from depredations, from destruction by natives or cattle, by means of suitable measures, such as the clearing of fire-belts, the establishment of small wattle plantations, the prohibition of wattle-cutting and cattle-grazing, with the aid of proper supervision and special legislation. (*c*) The closure of the forests pending survey, demarkation, and settlement. (*d*) The adoption of sound methods of forestry to secure a steady yield, improvement of the forest, and most profitable management. (*e*) The utilization of colonial woods for railway sleepers. (3) Plantations of conifers and hard woods, designed to supply the future requirements of the country, can be made profitably along railway lines in the upland and the midland districts. (4) The most urgent work of a Forest Department in Natal would be to save what is left of the native forests, and plantation work should be deferred till it can be undertaken without detriment to the progress of survey and demarkation.

IN the new number of the *Zoologist* there are some interesting notes, by Mr. R. J. Ussher, on crossbills in the county of Waterford. This spring he has had exceptionally good opportunities of observing the breeding habits of these birds, as four of their nests were found in his neighbourhood, three of them being within fifteen hundred yards of his house. Of the four male birds, three were red, or red interspersed with brown. One had yellow plumage, similar to that of a specimen which Mr. Ussher presented last year to the British Museum. This bird had all the appearance of having arrived at full maturity, being large, active, vigilant, and with mandibles conspicuously crossed. When Mr. Ussher climbed to the nest, both male and female perched within four feet of him, "calling excitedly." "On April 17," he says, "these crossbills were seen to carry bits of something in their mouths to the nest, as if to feed their young. The nature of the food has not been ascertained, but is suspected to be largely composed of the green opening buds of the larch, on which I have repeatedly seen the male feeding—*e.g.*, on April 4." Mr. Ussher thinks that crossbills are on the increase in Ireland at present.

IN the Journal of the Bombay Natural History Society (vol. iv. No. 3) Mr. E. Giles records a curious fact which ought to have some interest for entomologists. In June 1888 he was standing one morning in the porch of his house, when his attention was attracted by a large dragon-fly of a metallic blue colour, about 2½ inches long, and with an extremely neat figure, who was cruising backwards and forwards in the porch in an earnest manner that seemed to show he had some special object in view. Suddenly he alighted at the entrance of a small hole in the gravel, and began to dig vigorously, sending the dust in small showers behind him. "I watched him," says Mr. Giles, "with great attention, and, after the lapse of about half a minute, when the dragon-fly was head and shoulders down the hole, a large and very fat cricket emerged like a bolted rabbit, and sprang several feet into the air. Then ensued a brisk contest of bounds and darts, the cricket springing from side to side and up and down, and the dragon-fly darting at him the moment he alighted. It was long odds on the dragon-fly, for the cricket was too fat to last, and his springs became slower and lower, till at last his enemy succeeded in pinning him by the neck. The dragon-fly appeared to bite the cricket, who, after a struggle or two, turned over on his back and lay motionless, either dead, or temporarily senseless. The dragon-fly then, without any hesitation, seized him by the hind legs, dragged him rapidly to the hole out of which he had dug him, entered himself, and pulled the cricket in after him, and then, emerging, scratched some sand over the hole and flew away. Time for the whole transaction, say, three minutes.'

A CATALOGUE of the Birds in the Provincial Museum, N.W.P. and Oudh, Lucknow, has been printed by order of the Museum Committee. Like the previous catalogue, it records the purely Indian birds in the Museum, now 783 in number, represented by 5360 specimens. Mr. George Reid, who is in honorary charge of the natural history department of the Museum, says no pains have been spared to make the work both accurate and complete. "It contains, he believes, in a convenient form, all the information requisite to enable workers at a distance to avail themselves, if necessary, of the contents of the Museum; while it places in the hands of all an absolutely trustworthy record of localities for a considerable number of species, and so contributes to an accurate knowledge of their geographical distribution, which, after all, is, or ought to be, the primary object of all local catalogues."

MR. L. FLETCHER, F.R.S., contributes to the current number of the *Mineralogical Magazine* a valuable paper on the meteoric iron of Tucson. The other contents of the number, in addition to abstracts and a review, are:—The hemimorphism of stephanite: the crystalline form of kaolinite, by H. A. Miers; on zinc oxide from a blast-furnace, by J. Tudor Cundall; on zinc sulphide replacing stibnite and orpiment—analyses of stephanite and polybasite, by G. T. Prior; index to mineralogical and petrographical papers, by H. A. Miers.

THE Marine Biological Association of the United Kingdom has issued the third number of its Journal, and we need scarcely say that the papers present a record of much valuable work. The following are the contents:—The Director's Report, No. 3; the sense-organs and perceptions of fishes, with remarks on the supply of bait, by W. Bateson (with plate); notes on oyster culture, by Dr. G. Herbert Fowler (with plate); the generative organs of the oyster, by Dr. P. P. C. Hoek—abstract by G. C. Bourne (with plates); letter on oyster culture, by Lord Montagu of Beaulieu; flora of Plymouth Sound and adjacent waters (preliminary paper), by T. Johnson (with a woodcut); report of a trawling cruise in H.M.S. *Research* off the south-west coast of Ireland, by Gilbert C. Bourne; notes on the Echinoderms collected by Mr. Bourne in deep water off the south-west coast of Ireland in H.M.S. *Research*, by Prof. F. Jeffrey Bell; anchovies in the English Channel, by J. T. Cunningham (with an illustration in the text); notes and memoranda (with plate); and price list of specimens. In his Report, Mr. G. C. Bourne mentions that Dr. Dohrn, the founder and Director of the Naples Zoological Station, writing to Prof. Ray Lankester about the choice of a site for the laboratory of the Marine Biological Association, said that the source from which the sea-water was derived was not of so much importance as the size of the storage reservoirs, for no water that could be drawn from the sea would be as suitable for hatching and rearing delicate marine organisms as that which had been for some time in the reservoirs. "Our experience," says Mr. Bourne, "proves the wisdom of Dr. Dohrn's advice."

MESSRS. FRIEDLÄNDER AND SON, Berlin, have issued two numbers of *Abhandlungen und Berichte* of the Zoological and Anthropological Museum of Dresden. The first number includes an elaborate report, for the year 1887, of the ornithological stations in the Kingdom of Saxony, by A. B. Meyer and F. Helm; a paper on *Sus celebensis*, by A. Nehring; Lung Ch'üan-Yao, or old Celadon porcelain, by A. B. Meyer; Coleoptera collected in the years 1868–77 during a journey in South America by A. Stübel, arranged by T. Kirsch; and an obituary notice of T. Kirsch, by A. B. Meyer. The second number consists of a monograph, by Dr. K. M. Heller, on "Der Urbüffel von Celébes: *Anoa depressicornis* (H. Smith)." Both numbers are admirably printed and illustrated.

MESSRS. WILLIAM WESLEY AND SON have issued No. 100 of their "Natural History and Scientific Book Circular." It contains a list of works relating to entomology and botany.

MESSRS. JOSEPH TORREY, JUN., AND EDWIN H. BARBOUR, in a letter dated Iowa College, Grinnell, May 9, have sent to *Science* an account of a remarkable meteor, or meteoric shower, which passed over the State of Iowa on Friday, May 2, at 5.40 p.m. In spite of the brightness of the sun, shining at the time in a nearly cloudless sky, the light of the meteor was very noticeable.. Its great size, powerful illumination, discharge of sparks, comet-like tail 3° to 5° in length, and the great train of smoke which marked its course for fully ten minutes after its passage, made a strong and lasting impression on the minds of all who saw it. Unfortunately the clamour over an exciting game of ball prevented the many members of the college who saw it from making as careful observations as they would otherwise have done; so it was impossible to tell whether its passage was accompanied by sound or not, but farmers in the neighbourhood report a faint hissing noise. It appeared to enter the atmosphere about 20° to 30° south of the zenith, and descending at an angle of about 50° to 60°, passed below the horizon north-north-west of Grinnell. By telegraphing, one small meteorite, weighing one-fifth of a pound, and several fragments from a 70-pound one, were secured, and analyses and microscopic sections at once made. They contain a large amount of metal for the "stone" class of meteorites. The following is the analysis of the matrix of the 70-pound meteorite: silica, 47·03; iron oxide, 29·43; oxide aluminium, 2·94; lime, 17·58; magnesia, 2·96; total, 99·94.

MR. GEORGE F. KUNZ, writing to *Science* from New York on May 8 about the same meteor, says it was seen over a good part of the State of Iowa at 5.15 p.m standard western time. According to his account, the passage of the meteor was accompanied by a noise like that of heavy cannonading or thunder; and many people rushed to the doors, thinking it was the rumbling of an earthquake. The meteor exploded, he says, about eleven miles north of Forest City, Winnebago County, in the centre of the northern part of Iowa, lat. 43° 15′, long. 93° 45′ west of Greenwich, near the Minnesota State line. The fragments were scattered over a considerable surface of ground, and a part of the main mass was believed to have passed down into Minnesota. Up to the time at which Mr. Kunz wrote his letter, there had been found masses of 104 pounds, 70 pounds, and 10 pounds, and a number of fragments weighing from one to twenty ounces each. The pieces are all angular, with rounded edges. Mr. Kunz says the meteor is apparently of the type of the Parnallite group of Meunier, which fell February 28, 1857, at Parnallee, India. "The stone is porous, and when it is placed in water to ascertain its specific gravity, there is a considerable ebullition of air. The specific gravity, on a fifteen-gramme piece, was found to be 3·638. The crust is rather thin, opaque black, not shining, and, under the microscope, is very scorious, resembling the Knyahinya (Hungary) and the West Liberty (Iowa) meteoric stones. A broken surface shows the interior colour to be gray, spotted with brown, black, and white; the latter showing the existence of small specks of meteoric iron from one-tenth to four-tenths of a millimetre across. Troilite is also present in small rounded masses of about the same size. On one broken surface was a very thin seam of a soft black substance, evidently graphite (?), and soft enough to mark white paper; a felspar (anorthite ?) was also observed, and enstatite was also present." Mr. Kunz points out that this is the fourth meteorite that has been seen to fall in Iowa. The other three falls were as follows: at Hartford, Linn County, February 25, 1847; at West Liberty, Iowa County, February 12, 1875; and the great fall of siderolites at Estherville, Emmet County, May 10, 1879, which fall comprised over two thousand pieces weighing from a tenth of an ounce to 400 pounds.

A VALUABLE contribution to the study of the natural causes which check the tendency of plants and animals to increase in too great numbers appears in a recent issue of the *Bulletin* of the Moscow Naturalists (1889, No. 3). It is by Mr. Alexander Becker, whose ideas on the subject are based upon direct observation. For several years, various species of grasshoppers appeared in great quantities in South-East Russia (about Sarepta), but then came one year of sudden death for most of them: they were seen sitting motionless on the grasses, and dying. A few years ago the butterfly, *Melithæa Phœbe*, var. *ætherea*, appeared in immense numbers, and it was expected that in the following year it would be still more numerous, but in reality it became exceedingly rare. The like was true of *Zegris eupheme*, which

suddenly became most numerous in 1883, and disappeared in 1884; even in 1883 its caterpillars could hardly be found on the plants they usually feed upon. Some hostile influence had prevented its further multiplication. Similar facts have been observed in the case of Mammalia as well. The *Spermophilus citillus* is usually met with about Sarepta; but sixty years ago it suddenly disappeared in the course of one summer—probably succumbing to some contagious disease. During the following years it could hardly be found, but by and by it multiplied again to such an extent that each inhabitant of Sarepta had to undertake to kill every year a certain number of the *Spermophilus.* Their numbers were diminished, but still they are very numerous in the steppes, thus illustrating the small importance of even a systematic attempt at extermination, as compared with the importance of natural checks. Many birds suddenly appear in great numbers, and as suddenly disappear. The *Merula rosea* for several years nested in very great numbers at Sarepta. Mr. Becker also mentions interesting facts as to a yellow dust which spread over Saratoff in April 1864, and must have been brought from Central Asia. Under microscopical examination, it was found to contain a great number of germs and Infusoria. The seeds of *Typha stenophylla,* which formerly was never found at Sarepta, must have been imported quite recently by wind, either from Caucasia or Siberia. In the course of one summer this pretty plant became numerous in a pond in the Ergheni Hills, but it disappeared next year. As a rule, a decrease of all kinds of insects is noticed about Sarepta, and it can be explained only by the general conditions of weather resulting in indifferent crops, and a general diminution of hay crops in the surrounding steppes.

A COMPREHENSIVE paper upon the simpler derivatives of hydroxylamine, NH_2OH, by Drs. Behrend and Leuchs, will be found in the current number of *Liebig's Annalen* (p. 203). The great interest with which hydroxylamine derivatives have recently been invested by the discovery among them of geometrical isomers, and the considerable importance of hydroxylamine as a reagent for investigating the constitution of organic compounds, rendered it very desirable that something more definite should be ascertained regarding the compounds obtained by replacing the hydrogen of hydroxylamine by simple organic radicles, than the few isolated facts hitherto acquired. There are five types of derivatives possible, which are classified as follows, R representing a monad radicle: $H_2N—OR$ α-monalkyl, $RHN—OH$ β-monalkyl, $RHN—OR$ α-dialkyl, $R_2N—OH$ β-dialkyl, and $R_2N—OR$ trialkyl hydroxylamine. In the case of the radicle benzyl, $C_6H_5—CH_2—$, a complete series of such compounds have been prepared and fully investigated. The first member of the series, α-benzylhydroxylamine, $H_2N—OC_7H_7$, was prepared some time ago by Janny, and Drs. Behrend and Leuchs utilized Janny's reaction, improved very considerably in its details, in order to prepare this substance in quantity. The reaction consists in warming hydrochloric acid with the benzyl derivative of the well-known acetone compound of hydroxylamine, acetoxin, $(CH_3)_2C{=}NOH$. Its course may be represented by the equation $(CH_3)_2C{=}NOC_7H_7 + HCl + H_2O = H_2N—OC_7H_7 . HCl + (CH_3)_2CO$. The hydrochloride thus obtained crystallizes in large, flexible, lustrous plates, which sublime at 230°–260° C. without fusion. The free base itself, α-benzylhydroxylamine, $H_2N—OC_7H_7$, is a liquid which cannot be distilled at the ordinary pressure without decomposition, but at a pressure of 30 mm. distils unchanged at 118°–119°. It may also be safely distilled in steam. α-dibenzylhydroxylamine, $H(C_7H_7)N—O(C_7H_7)$, is readily obtained from the mono-compound just described by the limited action of benzyl chloride. It is also liquid at the ordinary temperature, and more difficultly volatilizable even in steam than the mono-compound. Its hydrochloride crystallizes well from alcohol in glittering needles. The di-compound is readily transformed by further action of benzyl-chloride into tribenzylhydroxylamine, $(C_7H_7)_2N—OC_7H_7$. The tri-compound is likewise a liquid, and is not volatile without decomposition even *in vacuo*. Its hydrochloride is readily and completely decomposed by water. The β-mono-compound, $(C_7H_7)HN—OH$, is obtained by boiling the α-di-compound with concentrated hydrochloric acid, or heating the two together in a sealed tube to 130°. $(C_7H_7)HN—O(C_7H_7) . HCl + HCl = C_7H_7HN—OH . HCl + C_7H_7Cl$. The free base, which is liberated as an oil upon addition of sodium carbonate solution to the concentrated solution of the hydrochloride, crystallizes on standing, and gives well-developed crystals on recrystallization from petroleum-ether. It also reduces Fehling's solution, in these two points differing markedly from the liquid α-mono-compound. The β-di-compound is best obtained by boiling hydroxylamine hydrochloride, benzyl chloride, and soda crystals with alcohol for an hour, using a reflux condenser. On cooling, crystals of the solid base are deposited, which melt at 123°. The preparation of this complete series shows in a very striking manner the different effects of substituting alkyl radicles for the hydrogen attached to nitrogen or for the hydroxylic hydrogen. The α-compounds are both liquids, while the β-derivatives are solids. The alkyl radicle replacing hydroxylic hydrogen is also very much more easily detached by the action of hydrochloric acid than that attached to nitrogen. It is also interesting to note that the basic character of hydroxylamine diminishes with the number of alkyl radicle groups introduced.

THE additions to the Zoological Society's Gardens during the past week include a Masked Parrakeet (*Pyrrhulopsis personata*) from the Fiji Islands, presented by Mr. Geo. Lawson; a Lanner Falcon (*Falco lanarius*), European, presented by Miss Marjorie Barnard; three Common Vipers (*Vipera berus*), British, presented by Mr. A. W. Cotton; two Andaman Starlings (*Sturnia andamanensis*) from the Andaman Islands, three Ceylon Fish-Owls (*Ketupa ceylonensis*) from Ceylon, six Tufted Ducks (*Fuligula cristata* 3 ♂ 3 ♀), European, purchased; a Great Bustard (*Otis tarda* ♀), European, received in exchange; two Japanese Deer (*Cervus sika* ♂ ♂), two Barbary Wild Sheep (*Ovis tragelaphus* ♂ ♀), a Burrhel Wild Sheep (*Ovis burrhel* ♂), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

OBJECTS FOR THE SPECTROSCOPE.

Sidereal Time at Greenwich at 10 p.m. on June 5 = 14h. 57m. 6s.

Name.	Mag.	Colour.	R.A. 1890.	Decl. 1890.

Remarks.

(1) The spectrum of this nebula has not been recorded. In the General Catalogue it is described as: "Very bright; pretty large; round; pretty suddenly much brighter in the middle to a nucleus; following of two." The companion is apparently very faint.

(2) This is a bright oval nebula under the body of Draco. Smyth states that it is "rather faint at the edges, but not so as to obscure the form." The General Catalogue description is "Very bright; considerably large; pretty much extended in the direction 146°; gradually brighter in the middle." In 1848

Lord Rosse observed a longitudinal rift, but this has not been confirmed by later observations. According to Dr. Huggins, the spectrum is continuous, but it is not at all unlikely that further observations may show that it is not entirely so. The whole nebula appears to resemble that in Andromeda, even to the dark rift, and we now know that the spectrum in that case is not perfectly continuous. Intending observers of this class of nebula spectra will do well to examine the spectrum of Comet Brooks, which was referred to in last week's notes. The spectrum of the comet is apparently continuous at first sight, but careful observation shows beyond question the existence of the usual flutings of carbon. These flutings may also be expected in the nebulæ having so-called "continuous" spectra.

(3) D'Arrest likens the spectrum of this star to that of β Pegasi, but Dunér thinks it more like α Herculis. All the bands 1–9 are very strongly marked, and are wide and dark. Observations similar to those suggested for other stars of the group are required.

(4) According to Vogel, this star has a well-marked spectrum of the solar type, but Dunér classes it with stars of Group II. He states that the bands 1–8 are seen, but that they are narrow and not very dark, 4 and 5 appearing as lines. He also suggests that the spectrum is an intermediate one between Group II. and Group III. As I have pointed out on previous occasions, it is these intermediate stages which require a detailed study. It is pretty certain that the passage from one group to another will not be abrupt, but that there will be intermediate stages between each successive two. The star in question is probably slightly less advanced in condensation than Aldebaran.

(5) This is a star of Group IV. (Konkoly), but in addition to the hydrogen lines, D and *b* are distinctly visible. The usual observations are required.

(6) The range of this variable is from 6·0–8·1 at maximum to 13·2 at minimum, in a period of about 302 days. The increase of light is very rapid, whilst the decrease is slow and irregular (Sawyer). The spectrum is a fine one of Group II., the bands 1–9 being wide and dark; 7 and 8 are especially remarkable (Dunér). The usual bright lines which are now expected to appear at the maxima of stars of this class should be looked for. The maximum will occur about June 12.

A. Fowler.

Actinic Light of the Solar Corona.—Prof. Frank H. Bigelow, in *Bulletin* No. 15 of the United States Scientific Expedition to West Africa, dated April 19, 1890, gives an interesting note on the law of distribution of the actinic light of the solar corona. His paper on "The Solar Corona, discussed by Spherical Harmonics," noted in Nature, vol. xli. p. 595, assumed that the surface distribution of the electro-magnetic potential was expressed by C cos θ, the constant representing the maximum, and θ the angular distance from the coronal pole; the visible lines of the corona being shown to coincide in direction with the lines of force generated under these conditions. It is now suggested that the corresponding equipotential lines denote the position and direction of the surfaces of iso-actinism as referred to the same pole, or, in other words, that the actinic brightness is directly proportional to the potential. From the discussion it follows that the poles become the critical points for examination as to the actinic intensity of the corona; the sky in the neighbourhood should also be examined with great care; these two results, combined with the visible linear distance of the contour of merging of the polar rays in the sky light, in terms of the radius of the sun corrected from the covering lunar disk when taken in combination with the formula for these surfaces, will enable the whole of the coronal light to be discussed as simple phenomena.

On the Rotation of the Sun.—Prof. N. C. Dunér has made a series of observations of the displacement of lines in the spectrum at the eastern and western edges of the sun for the purpose of deducing the time of rotation (*Astr. Nach.*, 2968). The observations were made from 1887–89 with a Rowland grating spectroscope of high power attached to the refractor of Lund Observatory, the distances between several lines in the a group of the solar spectrum at opposite edges of the sun being micrometrically determined. The results of the measures are given in the following table, where ϕ is the heliocentric latitude of the points on the sun's edge, v the velocity in kilometres with which the point on the edge approaches the earth, ξ the angle of rotation in 24 hours, and n the number of measures made in the different years:—

ϕ.	v.	$\xi \cos \phi$.	ξ.	n.
°		°	°	
0·4	1·98	14·14	14·14	107
15·0	1·85	13·19	13·66	104
30·0	1·58	11·31	13·06	104
45·0	1·19	8·48	11·99	106
60·0	0·74	5·31	10·62	107
74·8	0·54	2·45	9·34	107

These values of ξ, deduced from spectroscopic observations, show that the equatorial zone of the solar surface has a shorter time of rotation than zones in higher latitudes, the results agreeing with those found from sun-spot observations. The advantage of the method used by Prof. Dunér, however, lies in the fact that it allows observations of rotation to be made in the neighbourhood of the poles. A comparison of the spectroscopic and the spot observations shows that the former gives a slightly smaller velocity of rotation than the latter.

It may be remembered that the work done under the direction of Prof. Rowland at Baltimore showed that "the absorbing layer of gases by which the Fraunhofer lines are formed does not behave like the sun-spots, but is slightly retarded at the sun's equator."

Pulkova Observatory.—The magnificent volume issued in commemoration of the jubilee of the Pulkova Observatory has been received. In the volume an account is given of the 30-inch refractor and the Astro-physical Laboratory, and the twelve plates which illustrate it are worthy representations of an enviable reality. It is hardly necessary to say that the history of the Observatory is fully delineated, and that technical descriptions of the instruments are given, whilst Hermann Struve gives a long account of the determination of the instrumental constants. A *résumé* is also given of the work done in the Astro-physical Laboratory, and a comprehensive bibliography of the various astronomical, geodetical, and other studies that have been completed. Indeed, the whole of the splendidly finished work is a fitting memento of the jubilee that it celebrates.

Telluric Lines of the Solar Spectrum.—M. J. Janssen presented a note to the Paris Academy, on May 27, relative to some results he has obtained during a stay in Algeria, where he has been for about four months investigating the action of the atmosphere on the solar spectrum by means of photographs taken when the sun is on the meridian and horizon. The photographs were taken with the aid of a Rowland's grating, and isochromatic plates were used in order to obtain records of the less refrangible portions of the spectrum. The work is not yet finished, but M. Janssen notes that, without the purity of the heavens in Algeria and the continuance of favourable days, it would have been impossible to obtain any results.

Brooks's Comet (*a* 1890).—The following ephemeris computed by Dr. Bidschof is given in *Astronomische Nachrichten*, No. 2969:—

The brightness at discovery has been taken as unity.

NEWTON'S INFLUENCE ON MODERN GEOMETRY.

IN the appendix to his "Arithmetica Universalis" Newton states that a study of the ancient philosophers had led him to the inevitable conclusion that those early pioneers of science had introduced geometry in order to escape from needlessly long and laborious calculations. So, too, the author of the "Principia" had a predilection for graphic as distinguished from analytic methods. Indeed, anyone who has perused that great work will readily endorse the truth of this assertion. Yet Newton was born some forty years after the death of Viète and only eight before that of René Descartes, whose writings gave such a wondrous impulse to analytical studies.

During the closing period of the seventeenth, and nearly the whole of the eighteenth century, analysis reigned supreme; whilst graphic methods languished from the wilful neglect, nay even undisguised contempt, of the new philosophers. But at length men grew weary of abstract thought, and, as was quite natural after an undue pursuit of one branch of science to the exclusion of all others, a strong reactionary current in favour of concrete geometrical studies supervened. Then, as now, the question of the respective merits of the two methods gave rise to serious, not to say heated, controversy. But why sane people should quarrel and then fall out over a purely mathematical difference of this sort is quite as incomprehensible to a sober-minded critic as the passionate resistance shown to the postal reforms of Sir Rowland Hill was to the placid and imperturbable mind of Lord Melbourne.

The general weariness of the scientific mind, brought on by an excess of analytical work, prepared the way for a great revival of the graphic *culte*. Carnot, following to a certain extent the previous example of Simpson, courageously resolved to continue the work of Pascal, Newton, and Desargues. In consideration of his treatises on projective geometry and the theory of transversals, Carnot has a definite claim to be deemed the leader of this modern insurrection against the excessive use of analysis. Contemporary with him we find Monge, one of whose pupils, Poncelet, may be justly termed the author *par excellence* of modern methods. Since Poncelet's time the further

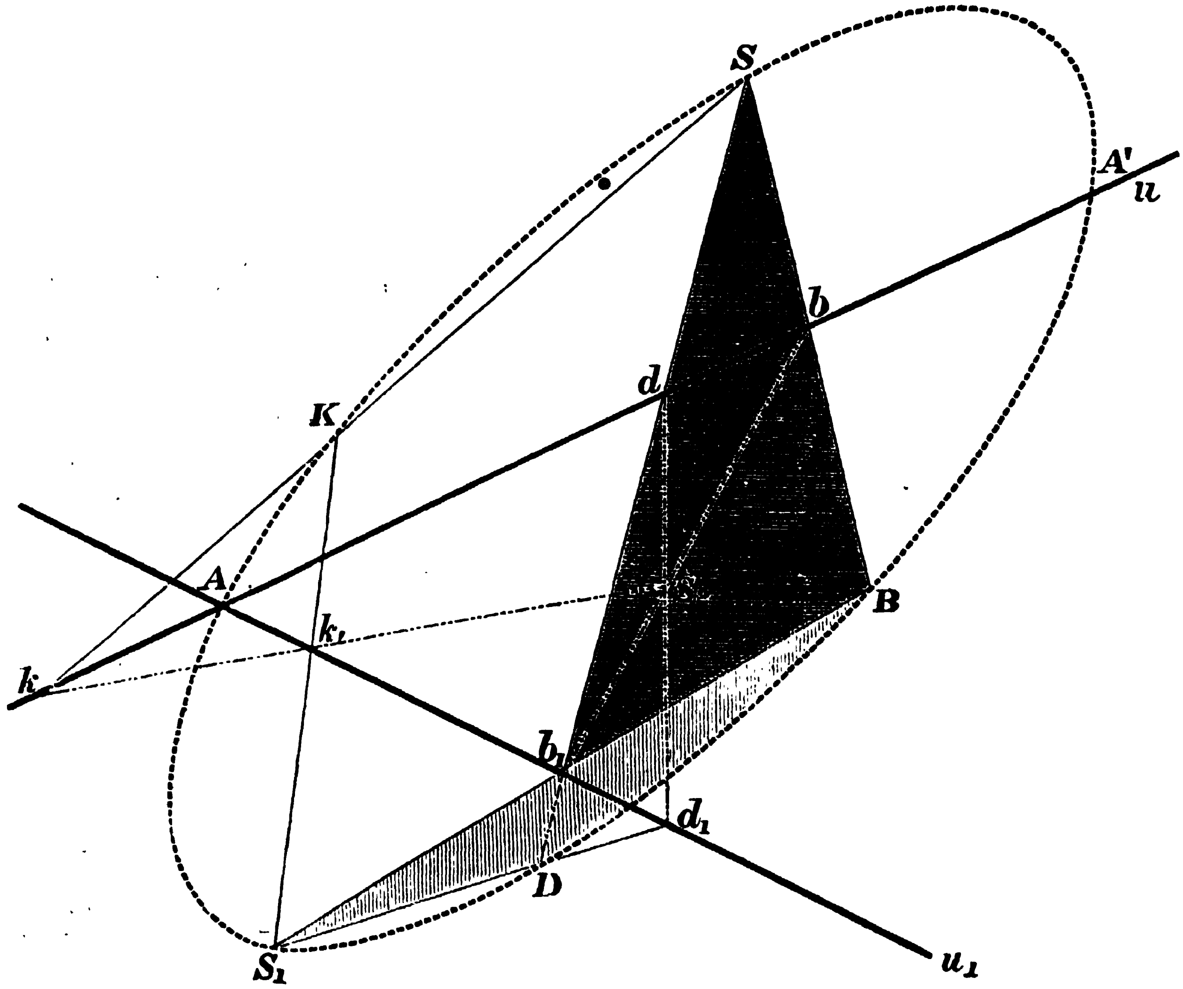

FIG. 1.

development of the system has been confined for the most part to Germany and Switzerland, under the guidance of such leaders as Steiner and Staudt. But, unfortunately, Staudt undertook the arduous, if not impossible, task of expounding projective geometry without the aid of diagrams, in regard to which Hankel well remarks, "that such an attempt was possible only in Germany, the land of scholastic methods and scientific pedantry."

Strange to say, Culmann, who was nothing if not a practical man of science, presupposes a knowledge of Staudt's geometry in all who would rightly understand his own epoch-making work on graphic statics.[1] Luckily, however, it is possible to understand every line of Culmann without having read a single word of Staudt. Now it is precisely the object of this paper to show that, in some of its more salient features, this so-called *Geometrie der Lage* is but a luxuriant offshoot of Newton's "Principia," in illustration of which we will here proceed to prove how the general method of constructing a conic, five points on which are given, may be deduced from the similar proposition in Newton. Further, in order to make the connection between Newton and Staudt more apparent, it will be advisable first to give the modern solution of the problem, and then show how the same solution can be geometrically deduced from Newton's principle.

SOLUTION.—Take any two of the given five points, for instance S and S_1 (Fig. 1), as centres of projection. Through a third point, A, draw any two lines u and u_1. Then, from the centre S_1, project the remaining two points B and D by rays S_1B and S_1D intersecting line u_1 in the points b_1 and d_1.

Similarly, from the second centre S, project the same two points B and D by rays intersecting the line u in b and d. Join bb_1 and dd_1, meeting in the centre of perspectivity, S_2, of the lines u and u_1.

Then, to find a sixth point on the curve, draw any ray through

[1] Published in the year 1864, not, as was recently stated in a contemporary, in 1866. The date is of importance when discussing priority of discovery in the matter of reciprocal figures; for Maxwell's paper on the subject in the *Philosophical Magazine* was also published in 1864. The question cannot, however, be discussed in a footnote.

S_2, intersecting u and u_1 in k and k_1; and project k from S and k_1 from S_1 by rays meeting in K, a point on the required curve.

PROOF.—Newton has solved this problem for a particular case, of which we will now give a short account, and thence deduce the more general modern method just described.

CASE I.—Let ABCD (Fig. 2) be a quadrangle inscribed in an ellipse, and P a point on the ellipse outside of the quadrangle; then, if PS and PQ be two chords meeting the sides of the quadrangle in S and T, R and Q respectively, the ratio

$$\frac{PR \cdot PQ}{PS \cdot PT}$$

will be constant for all positions of P. For, in the first instance, let PR and PQ be parallel to the side AC, PS and PT parallel

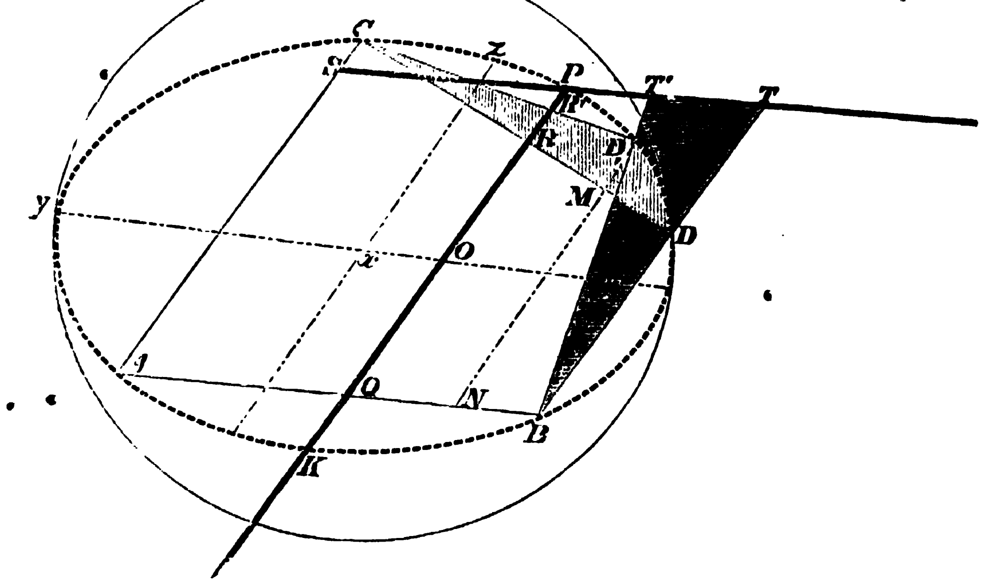

FIG. 2.

to the adjacent side AB, whilst the opposite sides AC and BD are parallel to each other. Owing to the parallelism of the sides AC and BD, a line bisecting those sides will be a diameter of the ellipse, bisecting the line RQ in O. The line PO will be the ordinate of P parallel to the axis conjugate of this diameter.

Now produce PO to K, making OK equal to OP; then K will be a point on the ellipse, wherefore—

$$\frac{PQ \cdot QK}{AQ \cdot QB} = \left(\frac{xz}{xy}\right)^2, \text{ a constant ratio.}$$

But

$$PR = QK,\ PS = AQ,\ PT = QB;$$

therefore—

$$\frac{PQ \cdot PR}{PS \cdot PT} = \frac{PQ \cdot QK}{AQ \cdot QB}, \text{ a constant.}$$

CASE II.—When BD_1 and AC are not parallel, draw BD parallel to AC, meeting the conic in D and the line PST in T. Join CD, intersecting PQ in R and D_1N, a line parallel to PQ, in M. Then, by similar triangles—

$$\frac{BT \text{ or } PQ}{TT'} = \frac{D_1N}{BN}; \quad \ldots \ldots \quad (1)$$

also—

$$\frac{R'R}{AQ \text{ or } PS} = \frac{D_1M}{AN}; \quad \ldots \ldots \quad (2)$$

whence, by multiplication—

$$\frac{PQ \cdot RR'}{PS \cdot TT'} = \frac{D_1N \cdot D_1M}{AN \cdot BN}. \quad \ldots \ldots \quad (3)$$

But, by Case I., since D_1 is a point on the ellipse and similarly situated with respect to M and N as P is with respect to R and Q, we have—

$$\frac{PQ \cdot PR}{PS \cdot PT} = \frac{D_1N \cdot D_1M}{AN \cdot BN}. \quad \ldots \ldots \quad (4)$$

Hence, from equations (3) and (4)—

$$\frac{PQ \cdot RR'}{PS \cdot TT'} = \frac{PQ \cdot PR}{PS \cdot PT};$$

or, by subtraction—

$$\frac{PQ \cdot RR'}{PS \cdot TT'} = \frac{PQ}{PS}\left(\frac{PR - RR'}{PT - TT'}\right) = \frac{PQ \cdot PR'}{PS \cdot PT'};$$

wherefore—

$$\frac{PR'}{PR} = \frac{PT'}{PT}. \quad \ldots \ldots \ldots \ldots \quad (5)$$

Thus, the lines R'T' and RT are parallel; so that, in order to construct the ellipse, it is necessary to divide the two lines PT and PQ by a series of parallel lines, meeting them in points T and R, which, being projected from the centres B and C respectively, will determine, by means of the points of intersection of corresponding rays, any number of points on the required conic.

Such is Newton's method of constructing a conic five points on which are given. We will now proceed to prove the intimate connection existing between it and the more modern method illustrated in Fig. 1, the discovery of which has been sometimes attributed to Pascal.

It will be observed that when, as in Fig. 2, the lines PT and PR are drawn parallel to the adjacent sides AB and AC, the rays R'T' and RT are parallel (5); and that, therefore, the centre of perspectivity of the punctuated lines PT and PR lies at an infinite distance. When, however, the lines PT and PR are shifted into the positions PT' and PR' (Fig. 3), being then no longer parallel to the adjacent sides branching from A, the points DEO on the ellipse are projected from B upon line PT' in $d_1e_1o_1$, and from centre C upon the line PR' in $d_1'e_1'o_1'$. Now, in order to demonstrate the method given at the beginning of this paper, it is necessary and sufficient to show that the lines joining d_1 and d_1', e_1 and e_1', o_1 and o_1', all meet in one and the same point, S; or, in other words, that the punctuated lines PT' and PR' are in perspective.

Thus, if the transversal o_1d_0 be drawn parallel to PT, we have—

$$\frac{o_1e_0}{oe} = \frac{d_0B}{dB}; \quad \frac{o_1e_1}{o_1e_0} = \frac{e_1P}{eP};$$

and, if the transversal $o_1\delta$ be drawn parallel to PR', we have—

$$\frac{o_1\epsilon}{o_1e_1} = \frac{e_1'P}{e_1P};$$

wherefore, multiplying together the right and left hand members of the last three equations, we obtain—

$$\frac{o_1\epsilon}{oe} = \frac{d_0B}{dB} \cdot \frac{e_1'P}{eP} \quad \ldots \ldots \quad (6)$$

Again, if $o_1'l$ be drawn parallel to AC or PR, we have—

$$\frac{o_1'e_1'}{o_1'\epsilon'} = \frac{e_1'P}{\epsilon'P}; \quad \frac{o_1'\epsilon'}{o'\epsilon'} = \frac{sl}{sP};$$

$$\therefore \quad \frac{o_1'e_1'}{o'\epsilon'} = \frac{e_1'P}{\epsilon'P} \cdot \frac{sl}{sP} \quad \ldots \ldots \quad (7)$$

Let

$$\frac{o'e'}{oe} = \frac{o'd'}{od} = n, \text{ a constant};$$

then, by eq. (7),

$$\frac{o_1'e_1'}{oe} = n\frac{e_1'P}{\epsilon'P} \cdot \frac{sl}{sP}; \quad \ldots \ldots \quad (8)$$

and, from equations (6) and (8),

$$\frac{o_1\epsilon}{o_1'e_1'} = \frac{1}{n} \cdot \frac{d_0B}{dB} \cdot \frac{\epsilon'P}{eP} \cdot \frac{sP}{sl}$$

$$= \frac{d_0B}{dB} \cdot \frac{sP}{sl} = k.$$

By a similar process of reasoning it can be shown that

$$\frac{o_1\delta}{o_1'd_1'} = k,$$

wherefore—

$$\frac{o_1\epsilon}{o_1'e_1'} = \frac{o_1\delta}{o_1'd_1'};$$

so that the lines e_1e_1' and d_1d_1' must meet in the same point on line o_1o_1', which point of convergence is therefore the centre of perspective, S.

The perspectivity of the punctuated lines PT′ and PR′ may be deduced from the projective relations of Fig. 3 by means of the following two well-known theorems of projective geometry.

THEOREM I.—If the correlative or coharmonic points a and a_1 of the punctuated lines u and u_1 (Fig. 4) coincide with their common point of intersection, forming what may be termed a coharmonic point, the lines u and u_1 are in perspective. For, let bb_1 and cc_1 be any other two pairs of coharmonic points, and meet in the centre S; then S will be the centre of perspectivity of the two lines u and u_1; seeing that in a harmonic or other system of ratios, any three members of a compound proportion

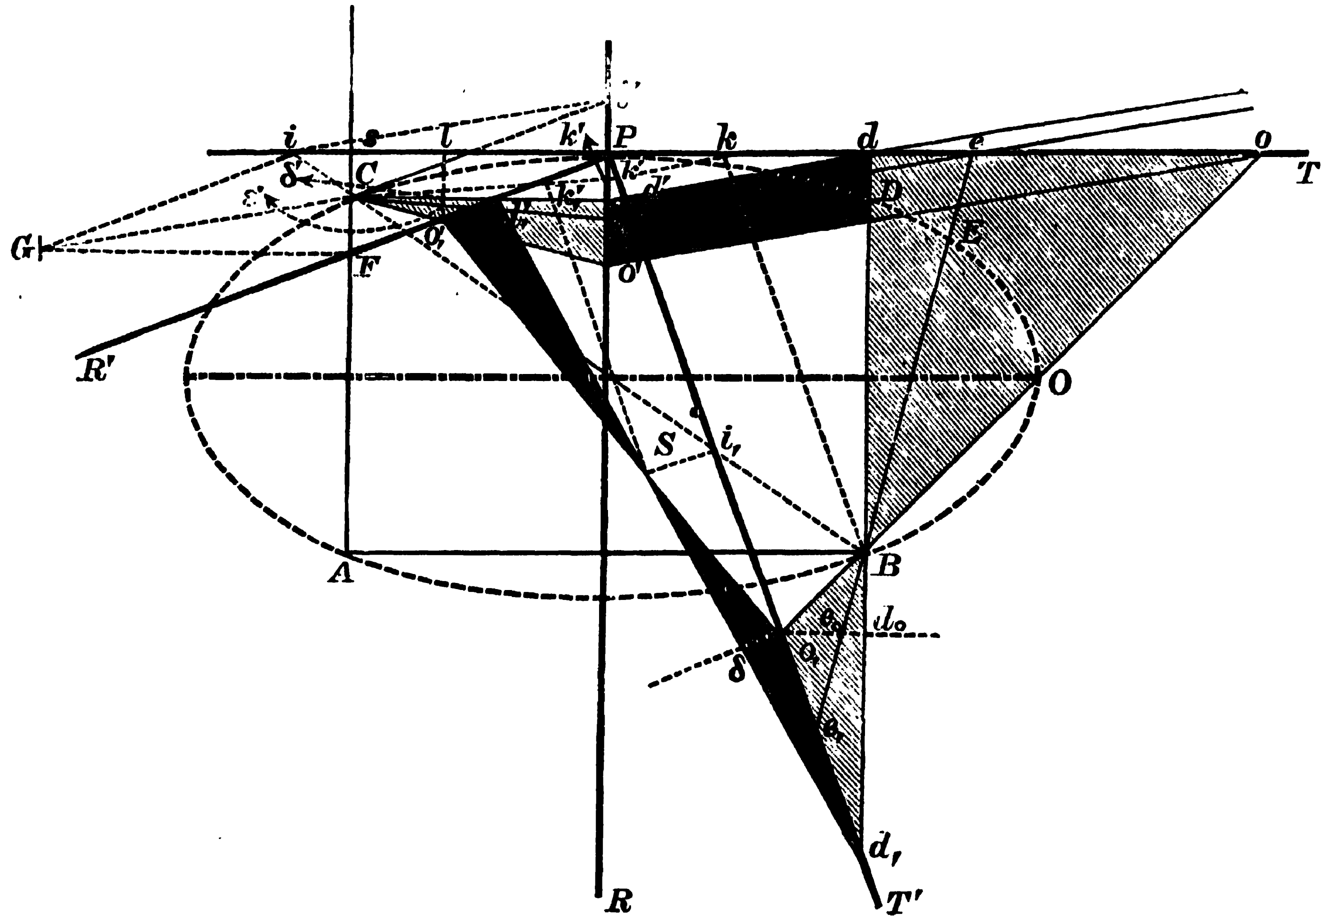

FIG. 3.

consisting of four terms suffice to determine the fourth or unknown term. Then, this fourth point, being known and taken in conjunction with any pair of the other three known terms, will serve to determine a fifth; and so on *ad infinitum*.

THEOREM II.—Similarly, if in Fig. 5 any pair of coharmonic rays Sa and S_1a_1 of two different pencils lying in the same plane are coincident or coperspective, the two pencils will be perspec-

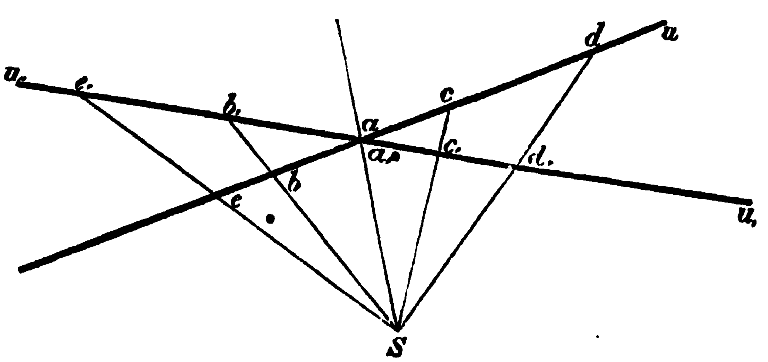

FIG. 4.

tive of the same line, and consequently perspective of each other. For, let the coharmonic rays Sb and S_1b_1 meet in a point B, and the rays Sc and S_1c_1 in C; then the line BC will be perspective of each pencil; seeing that, if three coharmonic rays of the pencils meet upon the line BC, it necessarily follows that a fourth pair of such rays will meet upon the same line.

Now it will be observed that lines PT and PR (Fig. 3) are in perspective, being projected from infinity on the right of the figure. So also are lines PT and PT′ as projected from centre B, and lines PR and PR′ as projected from centre C. Further, the point P is a coharmonic point common to lines

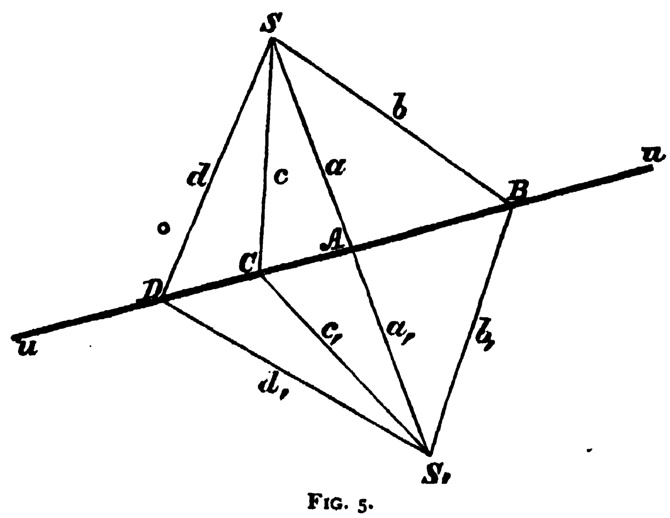

FIG. 5.

PT′ and PR′ as projected from centres B and C respectively; for it will be seen that P does not change its position when projected through centre B from line PT to line PT′, nor does it change when projected, first from infinity parallel to dd', ee', &c.

from line PT to line PR, and thence through centre C upon line PR′. Moreover, the point P is the point of intersection of lines PT′ and PR′; wherefore, by Theorem I., the lines PT′ and PR′ are in perspective.

In order to find the centre of perspectivity of lines PT′ and PR′, we have the point k on line PT correlative of the point at infinity on PT′, k being determined by drawing Bk parallel to PT′. The point k_1' on PR′, correlative of k on PT, is found as before by projecting k first upon PR in k' and thence upon PR′ in k_1'. Thus, the required centre of perspectivity must lie somewhere on the indefinite line joining k_1' with the point at infinity upon PT′. Again, the point i' on PR corresponds to the point at infinity on PR′, to point i on PT, and to point i_1 on PT′; hence the sought centre must lie somewhere on the indefinite line joining i_1 to the point at infinity on PR′; wherefore it coincides with the intersection of lines i_1S and k_1'S.

Similarly it can be shown that the lines PT and PR′ are in perspective; for the line drawn from C, the centre of projection for line PR′, to S_∞, the centre of projection for line PT, or, in other words, the line drawn from C parallel to dd', ee', &c., is a coharmonic ray common to both lines; therefore, according to Theorem II., the lines PT and PR′ are in perspective. The corresponding centre of perspectivity is determined as follows. When the line oo', moving parallel to itself, passes to infinity, or, in other terms, when the points o and o' pass to infinity on lines PT and PR, the ray Co' takes up the position CF, parallel to PR. Hence, F is the point on line PR′ corresponding to infinity on PT; wherefore the required centre must lie somewhere on the line through F parallel to PT. But i is the point on PT corresponding to infinity on PR′; therefore the centre must lie somewhere on the line through i parallel to PR′. Hence we conclude that it must coincide with the point of intersection of lines FG and iG.

In this short paper we have made an honest attempt to trace one filament of the great stream of modern science to its original source. The space at our service may not admit of much more. Still, such a study, however limited its scope may be, is interesting, not only on account of the novel nature of the demonstrations which the proof of connection involves, but even more because of the reflex light thus cast upon recent invention.

ROBERT H. GRAHAM.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The Observatory Syndicate Report as follows:—

That they have considered the proposal made in the Report of the Newall Telescope Syndicate for the purchase of an acre or an acre and a half of land adjoining the grounds of the Observatory for the erection of the Newall telescope and its appurtenances, and they are of opinion that, in view of possible future requirements of the Observatory, it will be desirable to secure now the larger area—namely, an acre and a half.

They have consulted the Bursar of St. John's College, and have learnt that the College is willing to sell to the University an acre and a half at the price of £250. Further, Prof. Adams has offered to contribute £100 towards expenses.

Under these circumstances the Syndicate recommend that Prof. Adams's generous offer be accepted, and that the Vice-Chancellor, on behalf of the University, be empowered to enter into an agreement with St. John's College for the purchase of an acre and a half of land adjoining the grounds of the Observatory.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 1.—"Photographic Determination of the Time-relations of the Changes which take place in Muscle during the Period of so-called 'Latent Stimulation.'" By J. Burdon Sanderson, F.R.S.

It is now forty years since Helmholtz published his fundamental experiments on the time-relations of muscular contractions. The purpose of this investigation was to ascertain "the periods and stages in which the energy of muscle rises and sinks after instantaneous stimulation"; the word energy being defined as the "mechanical expression of activity"; and one of the most important conclusions of the author was that, in the muscles investigated by him, contraction does not begin until nearly one hundredth of a second after excitation. This interval has, by subsequent writers, been called the period of "latent stimulation."

Helmholtz subsequently (1854) showed, by experiments of surpassing ingenuity, that during this period an electrical change of very short duration occurs, which culminates at about one two-hundredth of a second after excitation. The fact discovered by Helmholtz was further investigated by Bernstein in 1866, with the aid of the repeating rheotome, and subsequently (1875) by du Bois-Reymond, whose statement of the actual time-relations of the electrical response to an instantaneous excitation of the gastrocnemius of the frog is embodied in a curve which denotes that the muscular surface becomes negative to the tendon about three thousandths of a second after excitation, that this effect culminates at seven thousandths of a second, and that it is immediately followed by a change of opposite sign, which culminates at about ten thousandths.

By a new method—that of photographing in succession the mechanical and electrical responses in muscle on a rapidly moving sensitive surface—the author has shown that the mechanical response occurs much earlier than has been hitherto supposed; and that it is, in fact, simultaneous with the electrical change above described—that is, with the so-called negative variation.

The method consists in projecting the movement to be recorded, whether of the muscle or that of any instrument which serves as an index of change, on a vertical slit on which the vibrations of a tuning-fork and the motion of a signal are also shadowed. Immediately behind the slit is a photographic plate, which is carried by an equilibrated pendulum. The approximately uniform rate of motion of the sensitive surface which receives the light-written record is about one metre per second, but is determined in each experiment by reference to the rate of vibration of a tuning-fork.

In the experiments on direct excitation, the muscles used were the *gastrocnemius* and *sartorius* of the frog. In the former the movement of contraction was communicated to a light index, which was supported by a fine spring. One end of the index rested on the muscle, while the other occupied the front focus of a projection apparatus, the slit being in the other focus. When the sartorius was used the surface of the muscle was itself brought for a moment into the focus, at the seat of excitation. The unavoidable exposure of the structure to the electric light, which this method involved, lasted scarcely more than a second. In successful experiments, the interval between excitation and the beginning of the contraction was $2\frac{1}{2}$ thousandths ($= \frac{1}{400}$) of a second.

For measurement of the delay in indirect excitation, the gastrocnemius (with the index) only was used, the exciting electrodes being applied either at 12 or at 37 mm. from the muscle. The results were not so constant. Corrected for loss of time by propagation along the nerve, the intervals between excitation and beginning contraction varied from 0·0025″ to 0·0035″.

In the experiments for determining the time after excitation at which the electrical response begins and culminates, the capillary electrometer was used, as in the author's experiments on the heart and on the leaf of *Dionæa*, as a signal, but with much improved apparatus for recording.

In the gastrocnemius of the frog, the electrical response to an instantaneous stimulus is indicated by a sudden movement of the mercurial column of so short a duration, that to most persons it is invisible. Its photographic expression is that of a spike projecting from the dark border of the part of the plate which is unprotected by the mercurial column. The electrical interpretation of this spike is that between the contacts two electrical changes of opposite sign and not more than one two-hundredth of a second in duration have immediately followed each other, or, more explicity, that the spot excited became, for about 0·0005″, first negative, then for a similar period positive, to the other contact.

In the muscle (the leading off contacts being on the Achilles tendon and muscular surface respectively, and the nerve excited at a distance of 12 mm.) the electrical response begins at 0·004″ and culminates at about 0·012″ after excitation. Deducting the delay due to transmission along the nerve, we have, as the time between excitation and response, 0·0035″. It is thus seen that the electrical response, instead of preceding the mechanical, is

contemporary with it. The electrical change *may* therefore so far as concerns the time at which it occurs in muscle, be immediately connected with that sudden change of the elastic properties of muscle of which the contraction is the sign.

The author exhibited at the Society photographs in proof of all the facts above stated. Further details, particularly those relating to the character of the "electrical response" to instantaneous stimulation, for which the photographic method of recording the movements of the capillary electrometer on a rapidly moving surface has afforded new facilities, will be the subject of a later communication.

Anthropological Institute, May 13.—Dr. J. G. Garson, Vice-President, in the chair.—Mr. Francis Galton exhibited a new instrument for measuring the rate of movement of the various limbs. The method adopted was explained by referring to the action of a spring measuring-tape. When the end of one of these is pulled out and then let go, it springs sharply back, the tape running cleanly through a slit. If it runs back more quickly than the hand could follow it, then, if the end of the tape be retained in the hand that gives the blow, the tape will run through the slit at the exact rate at which the blow is given. The hand need not be near the tape; it may be connected with it by a long thread, and the instrument will thus be guarded from injury. The thread, during part of its course, is arranged to travel vertically, and passes through a small inverted cone which is fixed to it; it then passes loosely through a cylindrical bead of white ivory, the lower end of which rests on the base of the cone. When the moving thread is suddenly arrested, the bead is tossed up to a height dependent on the velocity of the thread at the time and place when it was stopped. The momentary pause of the white bead when it ceases to ascend, and before it begins to descend, enables the height it has attained to be read off upon an appropriate scale, which tells at how many feet per second the thread was moving at the time it was checked.—Dr. G. W. Leitner read a paper on the ethnographical basis of language, with special reference to the customs and language of Hunza. The Hunzas are nominal Mohammedans, and they use their mosques for drinking and dancing assemblies. There is little restriction in the relation of the sexes, and the management of the State, in theory, is attributed to fairies. No war is undertaken unless the fairy gives the command by beating the sacred drum. The people are not true Mohammedans, but represent what is still left of the doctrine of the Sheik-ul-Jabl, or the Ancient of the Mountain, the head of the so-called Assassins. The language of the Hunzas is one of the most primitive, and has not yet emerged from the state in which it is impossible to have such a word as "head," as distinguished from "my head," or "thy head, or "his head;" for instance, *ak* is "my name," and *ik* is "his name." Take away the pronominal sign, and *k* alone is left, which means nothing. *Aus* is "my wife," and *gus* "thy wife." The *s* alone has no meaning, and in some cases it seemed impossible to arrive at putting anything down correctly; but so it is in the initial stage of a language. In the Hunza language that stage is important to us as members of the Aryan group, as the dissociation of the pronoun, verb, adverb, and conjunction from the act or substance only occurs when the language emerges beyond the stage when the groping, as it were, of the human child between the *meum* and *tuum*, the first and second persons, approaches the clear perception of the outer world, the *suum*, the third person.—Mr. A. P. Goodwin read some notes on the natives of the interior of New Guinea, and exhibited a fire-stick.—Mr. G. F. Lawrence exhibited two crania from the Thames.

Geological Society, May 21.—Dr. A. Geikie, F.R.S., President, in the chair.—The following communications were read:—On some Devonian and Silurian Ostracoda from North America, France, and the Bosphorus, by Prof. T. Rupert Jones, F.R.S. After the reading of this paper Dr. Hinde said he wished to express the obligations of geologists to Prof. Jones for the excellent work which he had done amongst the Entomostraca; and particularly on the present occasion, for the clear manner in which he had explained the wide distribution of some of the species. The President alluded to the long years of arduous labour which Prof. Jones had bestowed on these minute fossils, and to the interesting results he had obtained from them.—On the age, composition, and structure of the plateau-gravels of East Berkshire and West Surrey, by the Rev. Dr. A. Irving.—Further note on the existence of Triassic rocks in the English Channel off the coast of Cornwall, by R. N. Worth.—On a new species of *Coccodus* (*C. Lindströmi*, Davis), by J. W. Davis.

PARIS

Academy of Sciences, May 27.—M. Hermite in the chair.—Note on the works of M. Louis Soret, by M. A. Cornu.—On the recent work done in Algeria, by M. J. Janssen (see Our Astronomical Column).—On meteorological observations made at mountain stations in Europe and the United States, by M. H. Faye. The author discusses some observations of temperature at various altitudes during cyclones and anticyclones, and the conclusions arrived at by M. Hann at Vienna, and Prof. Hazen in the United States, with respect to the variations found.—On the Turonian flora of Martigues (Bouches-du-Rhône), by M. A. F. Marion.—On the automatic resolution and integration of equations, by M. H. Parenty. An extract of a memoir presented by the author is given.—On the nutation of the axis of the earth, by M. Folie.—On the theory of heat, by M. Appell.—On the elliptical double refraction of quartz, by M. F. Beaulard.—On the conductivities of compounds of ammonia and aniline with the oxybenzoic acids, by M. Daniel Berthelot. One circumstance worthy of attention is that, in spite of the difference of conductivities of the three oxybenzoic acids, the conductivity of the mixture of equivalent parts of each acid and ammonia is almost the same for the three isomerides as for benzoic acid. The author has previously called attention to a similar fact in the case of salts of sodium. It is also noted that the conductivities of ammonium salts are superior to those of the corresponding salts of sodium.—Experiments on magnetization by single and double touch, by M. C. Decharme.—Researches on the dispersion of organic compounds (alcohols of the fatty series), by MM. Ph. Barbier and L. Roux. The authors show—(1) In the alcohols of the fatty series that they have examined, the dispersive powers are continuous functions of the molecular weights, and, contrary to what occurs in the aromatic series, *the dispersive powers increase with increase of molecular weight.* (2) The long-chain isomeric alcohols, primary and secondary, have sensibly the same dispersive power and obey the same laws; but the primary alcohols studied, other than normal, possess less dispersive powers, without, however, departing far from the values shown by long-chain alcohols. (3) The abstraction of hydrogen is accompanied by a considerable increase in the dispersive power.—M. Ed. Grimaux discusses the formula and reactions of homofluorescein.—On the employment of artificial sea-water for the preservation of marine animals, particularly oysters, in great aquaria, by M. Edmond Perrier. The solution recommended contains 81 grams sodium chloride, 7 grams magnesium sulphate, 10 grams magnesium chloride, and 2 grams potassium chloride, dissolved in 3 or 4 litres of water.—Observations on submarine vision, made in the Mediterranean by means of a diving apparatus, by M. H. Fol.—Two new hermaphrodite *Pélécypodes*, by M. Paul Pelseneer.—On the chemical examination of mineral waters from Malaysia; the formation of tin ore, note by M. Stanislas Meunier. An incrustation from the hot spring of Azer-Panas possesses the following composition: SiO_2, 91·8; H_2O, 7·5; SnO_2, 0·5; Fe_2O_3, 0·2; and traces of alumina. This is the first instance of the present formation of a tin-ore.—Observations on the structure of some ferruginous deposits of the Secondary rocks, by M. Bourgeat.—Discovery of a Turonian flora in the neighbourhood of Martigues (Bouches-du-Rhône), by M. G. Vasseur.—On the employment of copper salts as a remedy for the potato-disease, by M. Aimé Girard. The author demonstrates that a solution of sulphate of copper used as a preventive of the disease is very efficacious, and results in a gain in the quantity of the crop such as more than pays for the expense of treatment. Even when used purely as a curative agent, the yield of healthy potatoes is increased by 20·2 to 22·9 per cent.

BERLIN.

Meteorological Society, May 5.—Prof. Schwalbe, President, in the chair.—Dr. Kiewel spoke on the diurnal periodicity of the wind with special reference to Dr. Sprung's theory of the rotation of its direction. It appeared from his investigation that in addition to the influence of the sun's radiation, the variations of barometric pressure also produce a distinct effect, as also does the difference in the rate of the wind in the upper and lower layers of the atmosphere. A discussion followed, in which Dr.

Sprung took part.—Dr. Wagner announced that arrangements had been made for endeavouring to take simultaneous photographs of flashes of lightning at widely separated stations during the approaching summer. It was hoped that by this means, if successful, it would be possible to obtain some idea of the spacial and dimensional relations of the flash.

Physical Society, May 16.—Prof. du Bois-Reymond, President, in the chair.—Dr. Köpsel exhibited and described an apparatus for the calibration of the torsion-galvanometer of Siemens and Halske. The magnet which is used in that form of the galvanometer which is employed for technical purposes, frequently changes its magnetism in presence of other powerful magnets or currents, hence the instrument requires constant calibration and adjustment. Dr. Köpsel explained his method of effecting this with the help of a Clarke element. He further described a new form of resistance to be used in the measurement of very powerful electric currents. The older form, consisting of a brass tube filled with water, in communication with a reservoir of water, had proved useless in practice. The new resistances consist of nickel wires, surrounded by an insulating layer, inserted into a tube of lead and immersed in water. These wires were not rendered incandescent by currents of 80 to 90 amperes, and have been proved to be practically useful.

Physiological Society, May 23.—Prof. du Bois-Reymond, President, in the chair.—Prof. Falk gave an account of a case of a man who was found dead, and who must have died suddenly. A *post-mortem* examination showed that all the tissues and organs were in a normal state with the exception of the pancreas, which was infiltrated with blood. This he regarded as the cause of death, although it is as yet impossible to suggest how the lesion leads to death. Rupture of a blood-vessel in the pancreas is of rare occurrence.—Dr. Heymans had recently tested Engelmann's statement that the ureters contain ganglia at their upper and lower ends, but no nerves, employing the ureters of mice. Using gold chloride he observed, with low powers of the microscope, nerve-fibres accompanying the blood-vessels which surround the ureters. After removing the peritoneum and spreading out the excised ureters, he also found fine fibres between the muscle-cells, some of which appeared, under high magnification, to be attached directly to the muscle-cells. He was not able to make out that a nerve-fibril supplies each muscle-cell.—Dr. Bruhns gave an account of his researches on adenin and hypoxanthin, with a view to determining their chemical constitution; in this he has not as yet been more than partially successful. During his researches he came across a compound of adenin and hypoxanthin, whose properties explain many opposing statements of the less recent authors. The silver salts, with picric acid of the above bases, are the ones most suited for discriminating between them. Their salts with mercury are also extremely interesting from a chemical point of view, owing to their close resemblance to the amido-compounds of mercury.—Prof. Zuntz described a modified form of intestinal fistula which he and Dr. Rosenberg had recently applied.

BRUSSELS.

Royal Academy of Sciences, April 3.—M. Stas in the chair.—The following communications were made:—Researches on the volatility of carbon compounds, by M. Louis Henry.—On monocarbon derivatives, by the same author.—Reply to a note by General Liagre relative to M. Ronkar's work "On the Mutual Impulse between the Crust and Interior of the Earth on account of Internal Friction," by M. Folie. The criticism referred to appeared in *Bulletin* No. 3 of this year, and in reply to it M. Folie adduces proofs of diurnal nutation.—On the extent of the curative action of hypnotism: hypnotism applied to alterations of the visual organ, by M. J. Delbœuf, with the collaboration of M. J. P. Null and Dr. Leplat. An extended account is given of the treatment of a patient suffering from an eye-disease which was completely cured by hypnotism.—A new Nematoid of a Galago from the coast of Guinea, by M. P. J. Van Beneden.—Note on the law existing between unit of variation of vapour tension and absolute temperature, by M. P. De Heer.—On the structure of the equatorial bands of Jupiter, by M. F. Terby.—On the thickness of the earth's crust deduced from diurnal nutation, by M. E. Ronkar. From an extended investigation it is concluded that the thickness of the earth's crust does not exceed $\frac{1}{10}$ of the radius.—On the mutual impulse between the crust and interior of the earth on account of internal friction (second note), by the same author.—Experimental methods for determining whether polarized light, of which the plane of polarization is in vibration, exercises any influence on a magnetic field, by M. H. Schoentjes.—Experiments on the absence of bacteria in the ducts of plants, by M. Emile Laurent.

STOCKHOLM.

Royal Academy of Sciences, May 14.—On the discovery of Tertiary volcanic rocks near Lake Dellen in Helsingland and Lake Mien in Smaland, Sweden, by Dr. N. O. Holst and Dr. F. N. Svenonius. Specimens exhibited and commented upon by Baron A. E. Nordenskiöld.—Report on an entomological tour in Norrland and Jemtland, chiefly for the study of the Poduridæ of these countries, by H. Schött.—Some observations on the distribution of the sexes in the galls of *Andricus ramuli*, by Prof. C. Aurivillius.—On the Graptolithidæ of the island of Gotland, by Dr. G. Holm.—On the employment of indefinite determinants within the theory of linear differential equations, by H. von Koch.—Invariant expressions for the generalized substitution of Poincaré, by F. de Brun.—On a generalization of the functions of Klein of the third family, by G. Cassel.—The form of the integrals in linear differential equations, by A. M. Johanson.—Contributions to the knowledge of the Chlorophyceæ of Sweden, by O. F. Andersson.—Helminthological researches from the west coast of Norway, Part I., Cestoda, by Dr. E. Lönnberg.—Some Muriceidæ of the genera Acanthogorgia, Paramuricea, and Echinomuricea in the Zoological Museum of Upsala, by T. Hedlund.

ELECTRIC VERSUS *GAS LIGHTING.*

L'Éclairage Électrique actuel dans Différents Pays. By Jules Couture. (Paris: J. Michelet, 1890.)

IN this, the second edition of this pamphlet, a comparison is made between the prices of lighting by electricity and gas at Milan, Rome, Paris, Tours, Manosque, Perpignan, Marseilles, and New York. In Milan, the electric energy is either charged for by a fixed rate per lamp per year, plus a payment for each hour during which the lamp is turned on (the fixed annual rate and the hourly payment depending on whether the lamps be of 10 or of 16 candles), or the payment may be made to depend entirely on the consumption. In the latter case, however, the hourly payment per lamp diminishes with the number of lamps employed in the building, the rate per hour varying from 6 centimes for a 10-candle lamp if there be not more than 40 lamps, to 3⅞ centimes per 10-candle lamp if the number exceed 151. The incandescent lamps at Milan appear to require 6 watts per candle, and are therefore evidently specimens of the old Edison lamp; at the present day, however, there are lamps that can be incandescent with 40 per cent. less power, and still have a long life. In comparing the price of lighting by electricity and gas, M. Couture assumes that one Bengel gas-burner consuming 105 litres of gas per hour gives 10 candles. This is equivalent to 5·9 cubic feet per hour for 16 candles. Now a good Argand burner with London gas will give 16 candles for a consumption of 5 cubic feet per hour, whereas a common burner will not give more than 5 or 8 candles. M. Couture's typical burner and the Milan gas must therefore be good, whereas, as already mentioned, the incandescent lamps employed in Milan must be of an old character. Nevertheless, since electric lighting is supplied at 9 centimes per hour for a 16-candle lamp, and at 5·6 centimes (or about one halfpenny) in buildings using many lamps, the Milan Gas Company thought it wise to drop their price from 36 to 25 centimes per cubic metre of gas in the regions of the town supplied with electricity. For the benefit of readers who may study the copious information contained in this French treatise, we may mention that the London price of 2*s.* 6*d.* per 1000 cubic feet of gas is equivalent to almost exactly one penny per cubic metre.

In Rome, the Anglo-Roman Gas Company have utilized alternate-current transformers to distribute electric energy throughout the town from an electric station with 2700 horse-power, constructed on their own grounds, and have thus avoided the erection of expensive central stations in the town itself. The price charged is 8 centimes per hour for a 16-candle glow-lamp, and this M. Couture regards as a very remunerative one. It represents about 2½ times the cost in Rome of lighting with improved 16-candle Wenham gas-burners. M. Couture speaks of the two dynamos employed there as being the largest in the world, but, as they are only of some 500 horse-power each, it is clear that the author has not heard of the dynamos at Deptford, one of which has been running for some time, and which produces 1500 horse-power. Indeed, M. Couture is wonderfully silent about the electric lighting of towns in England, and makes no reference whatever to the prices charged for electric energy at various places in this country, or to the regulation of these prices by the systematic action of the Board of Trade.

Various installations employing transformers are referred to, amongst others that at Tours, and it is mentioned that the new price charged there for electric energy is only about 30 per cent. more than for an equivalent amount of gas. The only reference to electric lighting in Great Britain is to the first use of transformers when the Metropolitan Railway stations at "Edgard Road" and "Olgate" were experimentally lighted in 1883; and of the large amount of electric lighting work that has been carried out on the Continent by English engineers nothing is said, if we except the statement that "Badkok" and Wilcox boilers are used at Marseilles and at other towns. The value of the book, which is considerable, would have been increased if some reference had been made to "Sir Siemens" and "Sir Crompton," since certain large towns abroad, not mentioned in this book, owe their electric lighting to the exertions of these firms.

Formerly, electrical companies maintained installations at a loss, for the sake of advertisement; while gas companies, to avoid losing the streets that were lighted, have continued the lighting for a return less than the cost price. The financial results of electric supply companies have often not been sufficiently prosperous to enable interest to be paid upon the capital invested, but the same may be said of many gas companies in the early days of their existence. At Dijon, a central electric station has been rendered commercially impossible by the Gas Company dropping their price from 45 to 25 centimetres per cubic metre when they heard that the erection of one was contemplated.

The Marseilles Gas Company was the first gas company to establish a central station for the purpose of ascertaining the conditions under which the new method of lighting could be advantageously used in conjunction with gas and oil. Since 1881, when the Marseilles Gas Company first took up electric lighting, they have gradually extended their operations, so that to-day the electric lighting of the town is considerable. At the rates charged, it is 20 per cent. dearer to obtain 10 candles for 1000 hours in the year by electricity than with a *good* gas-burner; but if the time of lighting be extended to 2000 hours, electric lighting is only 6 per cent. dearer than gas lighting, and in the case of a 10-candle lamp lighted for 3000 hours in the year, electricity and gas come out equal in price. Consequently, if the gas be burnt in common burners, or if governors be not employed to keep the pressure of the gas constant, lighting with gas will actually be dearer in Marseilles than by means of electric glow-lamps. However, as the author points out, it is very important to see that a 10-candle glow-lamp really gives an illumination of 10 candles, since it is by the lamp, and not by the light, that the charge is made.

Electricity is, of course, now being much used where gas was formerly employed, but an interesting example is given in this book of electricity being resorted to for the lighting of a town in which gas could not be adopted. Manosque, in the Basses Alps, was lighted, up to 1888, with oil, the municipality not being able to introduce gas,

as nearly all the houses had cellars under the public street; but for the last two years the town has been lighted by means of electricity. The price charged is either at a fixed rate per month, independently of the number of hours the lamp is lighted, or the consumer can pay for the actual time the lamps are used at the rate of 5½ centimes per hour for a 16-candle lamp, 4 centimes for a 10-candle lamp, and 3½ centimes if the lamp be of 8 candles. It is interesting to notice that this charge of 5½ centimes per hour for a 16-candle lamp is almost exactly equivalent to 8*d.* per Board of Trade unit—the legalized rate for London.

At Perpignan, the prices per hour per lamp are the same as at Manosque, but if the lighting be charged at a fixed rate per month, the rate for a 10-candle lamp is either 3½ or 6 or 8 francs per month, depending on whether the lamp is put out every night at 10 o'clock or at midnight, or is left alight all night.

In Paris, gas costs 30 centimes per cubic metre, or, roughly, 7*s.* 6*d.* per 1000 cubic feet, while, for a 10-candle glow-lamp, 4·8 centimes per hour is charged; the user has also to pay an annual subscription of 4 francs, and he has to replace his lamp after 1000 hours at a cost of 4 francs. With these figures the author concludes that electric lighting with glow-lamps is 40 per cent. dearer than lighting with gas.

The largest single electric installations of *arc*-lamps is at Brooklyn, in America, where the Thomson-Houstin Company supply current for 1325. The following the author gives as the prices paid per hour for the current for one arc-lamp:—

Detroit	29 centimes.		
Paris	40	,,	
Milan	44	,,	if burning all night.
,, ...	50·2	,,	,, only until midnight.
Marseilles ...	52·5	,,	burning only until midnight.

To enable a comparison to be made, we have ascertained that the yearly price charged for the arc-lamps on the Parades of the English watering-places is equivalent to about 35 centimetres per arc-lamp per hour.

M. Jules Couture concludes his treatise in a very judicious manner as an old director of the Marseilles Gas Company:—"Little Jack Gas lives still, and will continue to live, I hope, for a long time yet. To prolong its existence, gas will not hesitate to inscribe on its banner, 'Gas-Electricity,' because its advocates are not at all adverse to progress."

The treatise forms a handy reference-book for those interested in the progress of electric lighting. It would have been well, however, if the author had given the price of *electric energy* in the various towns, instead of the price per ampere or the price for the current for a particular lamp. Constant reference is made to the supply of the light "*au moyen de compteurs*" in the various towns. Electrical engineers would have gladly welcomed some information as regards the character and the behaviour, satisfactory or otherwise, of the meters employed. We have already said that we think statistics of electric lighting in Great Britain might well have been added, seeing that it is now nearly two years ago since the Englishman's backwardness in taking up electric lighting began to disappear.

In justice to the consumers of gas, more stress should have been laid on the fact that ordinary gas-burners are very inefficient things. It might, for example, have been pointed out that, while as much as 6 candles per cubic foot of gas consumed per hour can be obtained with a Welsbach or with an albo-carbon burner, as little as ¾ of a candle per cubic foot consumed per hour is the meagre efficiency of certain twopenny-halfpenny nondescript burners. And if such a nondescript burner be ungoverned, as it probably will be, since people who have not the sense to buy good gas-burners are not likely to buy governors for them, then, when the pressure of the gas rises in the mains, the burner will not give more than ½ a candle per cubic foot. So that a burner passing 5 cubic feet of London gas per hour may give any illumination from 3 to 30 candles, depending on the nature of the burner.

In dealing, therefore, with the vexed question of the relative cost of lighting with electricity and gas, we must remember that, apart from glow-lamps causing much less damage than gas to books and decorations of rooms, lighting with glow-lamps at 8*d.* per Board of Trade Unit costs no more than lighting with ungoverned common gas-burners using gas at 2*s.* 6*d.* per thousand cubic feet. On the other hand, lighting with glow-lamps costs about 3 times as much as lighting with governed Argand burners, and 4 or 5 times as much as using albo-carbon or Welsbach burners.

A TEXT-BOOK OF GEOLOGY.

The School Manual of Geology. By J. Beete Jukes, F.R.S. Fifth Edition. Edited by A. J. Jukes-Browne, B.A., F.G.S. (Edinburgh: A. and C. Black, 1890.)

THE title and success of this handy little book lead one to inquire how far and where geology is taught in schools. There is no doubt that the subject has for scholars, particularly in the country, the strongest fascination; and the fine museum of Marlborough is an example of how "natural history" studies may be kept alive in seats of youthful learning. But it would be interesting to know how many schools, excluding special evening-classes, can give such a work as this a place in their curriculum, and thus carry back the history of England, Rome, and Greece to the earliest dawn of life upon the globe. The preliminary training for the appreciation of geological features such as every lad can see around him need not be excessively severe; the mere appreciation is at first the great thing—the knowledge that there is something to be learnt in road-side quarries, in familiar hollows of the hills, beside which the "Dictionary of Antiquities" seems like a fashion-book of yesterday; while at the same time, perhaps, the kinship of the boy with his favourite classic hero becomes something more real and inspiriting in face of the enormous past beyond them both.

While the work before us is a concise and convenient text-book, we suspect that, from mere force of circumstances, it aims more at the individual student than at the school-boy and the class. Just as William Smith, at the beginning of the century, pleaded for geology as a study advantageous to land-owners, so the editor appeals in his preface to the practical good sense of parents. The

claims of education in natural history as a means to individual and mutual happiness are perhaps too well known to need assertion; at any rate, it is not fashionable to put them forward.

For schools, one would like in this book a little more of the breath of the open country, such as appears in the few lines descriptive of the Cotteswolds; but the direct appeal to Nature in chapter ix. is very refreshing and characteristic of the author. Where, indeed, the work has been altered from the first edition of 1863, it is in matters of more recent discovery, its tone being fully preserved. Some little notes have gone, such as that on the difficulties of the Welsh "ll" on p. 216 of the original (p. 261 of the present edition is more serious); but the references to history and familiar authors remain, even to Wilkie Collins, while the introduction of derivations has been considerably and interestingly extended. Quaint effects in such matters cannot always be avoided, as in the following (p. 247), "Illænus (*squint-eye*) Davisii (*after Mr. Davis*)."

It is difficult in such a book to deal with rival theories; but the discussion of coral-islands, carried over seven pages, scarcely does justice to Darwin's position, and is certainly not complete—as in accounting for the atoll—in its statement of more recent views. Nor can we consider the treatment of the specific gravity of the earth (p. 8) as altogether beyond question, accepting as it does the continuous compressibility of crystalline bodies.

To come to small matters, the use of "potash" in different senses on pp. 46 and 48 may mislead the tyro; the spelling "tachylite" is adopted for "tachylyte"; and "Protospongia fenestella" for "fenestrata" occurs on both p. 238 and p. 239. On p. 329 we have, freshly inserted, the Pterodactyl from Owen's "Palæontology." This figure, arising from the difficulty of interpreting some of the earlier specimens, still appears in well-regulated text-books, but is sometimes accompanied with warning foot-notes; here it is aggravated by having its digits numbered, and the existence of a fifth, "answering to the little finger in our own hands," is distinctly stated in the text. But the other woodcuts are numerous and effective; and we have a few bold drawings of natural features as they actually appear, which always appeal strongly to the untrained observer. It is too much to ask for full-page sketches of our British scenery; but we look back in this matter somewhat regretfully on that earlier work of Jukes, the "Popular Physical Geology," illustrated by Du Noyer, and published with undoubted spirit by Reeve and Co. in 1853. G. C.

OUR BOOK SHELF.

Magnetism and Electricity. By W. Jerome Harrison, F.G.S., and Charles A. White. (London: Blackie and Son, 1890.)

WE note one or two features in this work which make it worthy of commendation; for example, the authors have avoided speaking of magnetic or electric fluids, and have endeavoured to bring out the fact that these forces are but "states or affections of matter," and their endeavour is much to be praised. It is also good to see an introductory chapter on "Matter and Force," and a special chapter on "Potential," about which elementary students, as a rule, know very little. Most of the diagrams, however, are of the stock kind, and with the exception of the above points the book possesses nothing to distinguish it from many other elementary manuals dealing with the same subject

Science applied to Work. By John A. Bower. (London: Cassell and Co., 1890.)

THERE is much that is praiseworthy in this little work; it is an easy introduction to mechanics, and free from all mathematical formulæ, is written in very clear language, and deals entirely with the mechanics of every-day life. The book has been designed especially for the artisan section of the National Home Reading Union, and will doubtless be a means of eradicating the rule-of-thumb work which is still characteristic of a large proportion of the artisan community. Many hints are given for making simple apparatus to demonstrate the principles laid down, the applications of these principles are well pointed out, and the work altogether meets the requirements of the class for whom it is intended.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Testing for Colour-Blindness.

DR. OLIVER LODGE asks (May 29, p. 100) why those interested in testing for colour-vision do not employ Lord Rayleigh's arrangement, in which yellow is matched by certain proportions of red and green.

This suggests to me a difficulty I have felt for many years. I am partially colour-blind, and have the usual difficulty in seeing whether a fuchsia or a *Pyrus Japonica* is in flower or not. I have noticed that many persons speak of flowers such as *Lychnis flos-Jovis*, or *Epilobium angustifolium*, &c., as being red. I should unhesitatingly class them among blue or purple flowers. They give me no suggestion of red, but I observe that when they are coloured in botanical works, such as Sowerby's "Botany," &c., they are painted of a decidedly reddish colour, and not as they appear in Nature. I used to attribute this to carelessness, but it is now evident to me that two colours which when placed side by side appear identical to normal vision do not appear at all identical to the colour-blind. Doubtless pigments could be found which would produce similar impressions on both orders of vision, but this is only a matter of chance. An investigation on these lines might give useful information.

On the question of flag signals, I would observe that though I can make nothing out of the ordinary dull greens, reds, and browns, and am ready to believe anything that is told me about them, my impressions of scarlet and orange are intensely distinct and vivid. Scarlet (and especially orange scarlet) is the most vivid and beautiful colour which I know, and utterly unlike any other; it becomes nearly black in very faint twilight. I could recognize a flag of scarlet or orange under any possible circumstances and at almost any distance. If danger flags had this colour they would perfectly suit the ordinary colour-blind, and could never be mistaken for green.

On the subject of night signals I cannot make a useful suggestion. Green lights are very distinct, but they appear to me as a poor blue with very little power in them. Red lights are distinct enough compared side by side with ordinary yellow ones, but seen alone under unfavourable circumstances there is nothing to catch the eye or the imagination, and they might easily be mistaken for yellow or ordinary lights.

London, June 9. LATIMER CLARK.

Coral Reefs—Snail Burrows.

IN regard to Dr. von Lendenfeld's letter (May 29, p. 100) it may suffice for me to say that I had not seen his reviews of Darwin's "Coral Reefs" in the periodicals which he names (for I find it impossible to keep level with the advancing flood of scientific literature), and that if his reply "considerably modifies

the meaning" of what I wrote, I must leave it to others to settle whether this be in a favourable or an unfavourable sense.

Turning to another matter: in reference to an interesting paragraph on p. 110 concerning the excavation of rock by snails, a subject on which I once wrote (*Geol. Mag.*, 1869, 1870), may I ask whether any of the readers of NATURE are acquainted with instances of these burrows occurring in non-calcareous rocks? All which I have seen were in limestone, and, as I believe, always in a pure variety. Hence, in the case of snails, one would suspect that the excavation was mainly due to chemical action. T. G. BONNEY.

Coral Reefs, Fossil and Recent.

I SUPPOSE it will be expected of me that I should answer the two objections raised by Captain Wharton (May 22, p. 81), viz. (1) that he knows of no steep submarine reef-slopes exceeding 4000 feet in height; and (2) that the lagoons could not be so shallow as they are if we assumed any extensive positive shifting of the coast-line.

From the statements in the literature on the subject, concerning point (1), I select the following three:—

Captain Fitzroy found at the Keeling no bottom 2200 yards from the breakers with a line 7200 feet long (Darwin, "Coral Reefs").

Bourne says in his account of Diego Garcia (Proc. Roy. Soc., vol. xliii.), that the Maldives, Laccadives, and the Chagos rise from a bank 1000 fathoms below the surface very abruptly.

Heilprin ("Bermudas") states that the Bermudas rise abruptly out of a depth of 12,000 to 13,000 feet.

Concerning point (2), I cannot see why the gentle inward slopes of atolls should not be in harmony with the subsidence theory. It must be borne in mind that the shifting of the coast-line is both slow and oscillating. Positive and negative shiftings alternate. The latter predominates on the whole. Dr. Murray says that in shallow water the accumulation of material exceeds the removal by solution. I have professed my accordance with this view in my previous letter. Particularly in an inclosed or partially inclosed lagoon, sheltered from ocean currents, this filling-up process will be a rapid one. We can easily conceive that it will balance the subsidence until the lagoon becomes so shallow as to impede the life of those organisms whose skeletons form the raising-up deposit. If there is any oscillatory negative shifting of coast-line, the dry rim will rise, and extend horizontally, and afford to the atmospheric agencies a larger surface wherefrom material can be washed into the lagoon.

On the whole, if there is anything difficult to explain, it is that the lagoons are as deep as they are. Deep lagoons are, however, not common, and are generally only met with in large and interrupted atolls. Perfectly dry central depressions (with deposits of gypsum and the like) are by no means infrequent in very small atolls. The general proportionality of the depth and the horizontal extent of the lagoons is perfectly in accordance with the subsidence theory. It supports no other theory better than this one. R. VON LENDENFELD.

Photographs of Water Drops.

IN NATURE of May 22 (p. 95) there is an account given of the discussion following Mr. C. V. Boys's demonstration of his photographs of falling water drops at the meeting of the Physical Society. In the course of this discussion, Lord Rayleigh, who was naturally much interested in the subject, remarked that it had never occurred to him that it would be possible to get enough light from a single spark to photograph the drops as Mr. Boys had done. And Lord Rayleigh believed Mr. Boys's success was owing to the fact of his using no lenses, which would absorb the ultra-violet rays.

With reference to this, it might, perhaps, be interesting to mention that I succeeded very well, some years ago, in photographing water drops, falling through air, with single sparks, the light of the spark passing two glass lenses and the objective of a camera which gave magnified images. My photographs (copies of which appeared in the *Annalen der Physik und Chemie*, vol. xxx., 1887) show all the forms obtained so very beautifully by Mr. Boys. From photographs taken at different depths below the orifice of the tube I could measure the periodic time of the elliptical vibrations and of the vibrations according to the next higher spherical harmonic, and show that the ratio of these two periodic times agreed very closely with the formulæ given by Lord Rayleigh in the Proc. Roy. Soc., 1879. The amplitudes had no influence upon the periodic times.

Richmond, Surrey, June 6. P. LENARD.

THE CLIMATES OF PAST AGES.[1]

I.

IT happens sometimes in the history of science that a few striking facts lead to the building up of a far-reaching theory, which at first satisfies us, and with which, without being rigorously critical, we endeavour to bring the further results of experience into conformity. But contradictions and difficulties gradually manifest themselves, and go on accumulating, until at last we are convinced that we have built on an unsure foundation, and that the edifice that we have raised upon it must be utterly pulled down. Then follows a period of discussion and collection of further evidence, during which we abstain from any attempt to substitute new and more correct explanation for that which we have abandoned, until by assiduous labour we shall have prepared a broader and more stable basis for the superstructure.

In such a stage of transition, the old ground abandoned, the new not yet won, is our knowledge of the climatic conditions of our earth in bygone ages. In the far north a rich mass of fossilized plants and coal-beds had been found in the Carboniferous formation. Reef-building corals, such as to-day live only in tropical seas, were yielded by the Carboniferous limestone and the Silurian formation up to 80° of northern latitude; and many of the species were found to range, without any essential change of form, from arctic to temperate, nay in some cases even to equatorial regions. From a small number of data such as these it was hastily concluded that, under the influence of the internal heat of the earth, a warm uniform climate must have prevailed generally from the pole to the equator, while a sultry atmosphere, heavily charged with water vapour and carbonic acid, prevented the sun's rays from reaching the earth or in any case from exercising any considerable influence on it. As a consequence, the existence of climatic zones or of a distribution of the fauna and flora in such zones was denied. It was held that with the beginning of the Tertiary era a polar cooling first set in, and that it increased during its passage, until the present distribution of heat was brought about as the final result of this long-continued process.

The falsity of these assumptions is now pretty generally recognized, and the number of their adherents diminishes daily. It would lead us too far afield were we to follow out the hypothesis into all the details of its ofttimes fantastic errors, and to note their individual failure. It will be more to the purpose if, in the first place, we test the methods by which we arrive at conclusions on the temperature conditions of past ages, in order that we may thus gain a knowledge of what these really were and of the better-grounded attempts to explain them.

Among the more important data for judging of the climate of a past epoch, is the character of its plants and animals, on the assumption that these various organisms must have lived under nearly the same conditions of temperature as their nearest relatives now existing. This kind of reasoning has been very extensively applied, and within certain limits its validity cannot be gainsaid. If, for instance, in a comparatively recent deposit of the Pleistocene period in Central Europe, we find remains of the arctic willow, the dwarf birch, the white dryas, together with such mammals as the lemming, the musk-ox, the

[1] Translation of a Lecture delivered by the late Dr. M. Neumayr before the Society for the Dissemination of Natural Science, at Vienna, on January 9, 1889.

glutton, the arctic fox, and also certain snails which, at the present day, live in Lapland or the higher Alps, we may safely conclude that a severe climate formerly prevailed there. An example of the opposite kind is afforded us by the later Tertiaries, which belong, indeed, to a considerably earlier but still not very remote period. Here we find, in our own neighbourhood, a flora of plants with evergreen coriaceous leaves, such as now grow in the warmer parts of the Mediterranean area, and we are quite justified in concluding that a higher temperature was once here prevalent. But, although in many cases such conclusions are well founded, a universal extension of this kind of reasoning leads to deceptive results, and the whole method must be applied with the greatest caution.

In the first place, we must bear in mind that, even at the present day, some forms that are nearly related to each other live under very diverse conditions. Antelopes, for instance, are for the most part animals characteristic of warm regions, and yet a kind of antelope, the chamois, lives in a very severe climate in the high mountains of the temperate zone. The arctic fox lives in the far north beyond the polar limit of trees, the Fennec in the burning African desert, and yet the two are nearly related to each other. The elephant and rhinoceros are at the present time peculiar to hot countries, and yet we know from unmistakable evidence that species of both these genera prevailed in Europe and Northern Asia in the cold Pleistocene climate. We have similar instances among marine animals, and we may adduce a whole series of cases in which a group of forms is predominantly peculiar to a certain kind of climate, but have individual representatives living under totally different conditions. The molluscous genera *Voluta* and *Terebra*, for example, are among the most characteristic inhabitants of warm seas, but each of them has a representative in the icy waters of the Magellan's Straits. And among land plants we have the remarkable fact that many forms of the north temperate zone, when they have been transplanted or have escaped to far warmer regions, have extended in an extraordinary manner, and locally to such an extent that they have overpowered and displaced the indigenous flora, as has occurred with the most diverse species of European weeds when transported to foreign countries.

On the whole, we are inclined to infer that, with the exception of the Pleistocene fauna and flora, the animal and plant remains of past ages, in their generality, point to a warmer climate than that which we now experience; and in point of fact, several very striking items of evidence lead to that conclusion. The most important is the very great extension of reef-building corals in the older deposits, while their modern representatives are restricted to the warmer seas.

Many other instances of the same kind may be quoted, while in other cases similar conclusions have been somewhat uncritically based on insufficient evidence. Thus, some have inferred the prevalence of a high temperature from the abundance and occasional great size of the chambered-shelled Cephalopoda, solely because the last existing representative of this once widely distributed group, the well-known Nautilus, happens to live in a warm sea. This conclusion is quite unjustified, for it is obvious that the many thousands of extinct species must have lived under very varied conditions; and if we are to infer, from the great size of these creatures, that they lived in warm seas, we ignore the fact that the largest Cephalopoda of the present day, the cuttle-fishes, are most prevalent in the northern part of the temperate zone.

But even when we have excluded all such evidently erroneous cases, the number of those in which fossil forms do really present the characters of types highly characteristic of warm regions is very considerable. It is true, that the opposite case sometimes presents itself, though less frequently. Thus, in all the older formations, a group of Bryozoa, the Cyclostomata, is extensively distributed, but it is now especially preponderant in the circumpolar seas. The molluscous genus *Astarte*, so common and widely distributed in Mesozoic deposits, is at the present day entirely restricted to cold seas; and there also occurs the last representative of the once widely spread genus *Cyprina*. The Brachiopodous genus *Rhynchonella*, common in the Silurian formation, and especially abundant in the Jurassic and Cretaceous formations, is now a form of high northern latitudes, and the Squaloid genus *Selache*, now restricted to the seas of Greenland, occurs in Cretaceous deposits in much more southerly latitudes.

Such instances, and they are far from singular, teach us, unmistakably and assuredly, that animal and vegetable types are not unchangeable in respect of the external conditions of their existence, and especially of temperature, but that they are capable of accommodating themselves to changed circumstances. Whether, then, we infer that reef-building corals formerly lived in cooler waters, or that Cyclostomoid Bryozoa frequented warmer waters than at the present day, or finally that both have changed their habit of life, the conclusion is overwhelmingly forced upon us that organisms continually adapt themselves to changed temperatures, and in a far higher degree than has generally been supposed.

In connection with this, we may notice a very remarkable circumstance, viz. the great vitality, adaptability, and toughness of the organisms of the temperate and especially the north temperate zone, when transported to other parts of the globe. Just as European man carries on a successful struggle with the children of all other zones of the earth, so also do the animals and plants indigenous to Europe, and especially those of its central and northern parts. As already remarked, when they are transplanted to foreign countries, they extend rapidly, and often drive out the indigenous forms; English naturalists who have had most opportunities of observing these relations in their colonies, speak expressly of the great aggressiveness of North European organisms.

At the present time, when the dissemination of the most diverse forms is brought about in the highest degree by world-wide human intercourse, such displacements present themselves in a particularly striking manner, and yet similar processes must have gone on, more slowly indeed, but on a far greater scale, for many millions of years. At some given epoch, a certain assemblage of organic forms appears in moderately cold regions, from which colonists wander away southwards; these gradually adapt themselves to the new local conditions, and spread still further, until, at last, their further progress is stayed by some natural barrier. They become acclimatized under the new conditions and the higher temperature, and become enfeebled; but in the meantime new forms have been developed in their former home, which in their turn pursue the same course and suffer the same fate; and thus the southern types always display a certain relationship to the older forms of the northern region, without any change having supervened in the temperatures of their respective stations.

We now see with how great caution we must proceed, when we attempt to draw any inference as to the temperature of former ages from the relationship of species, stratigraphically remote, with those of the existing organic world. The danger of error is here very great, and it is the greater and more menacing, the older the deposit the climatic conditions of which are in question; obviously, the probability of a change having taken place in organic constitution with regard to temperature is the greater, the more remote the epoch with which we are dealing. While, therefore, we may deduce conclusions having some claim to probability, on the climatic conditions of Pleistocene and Tertiary times, even in the Mesozoic

deposits such conclusions become doubtful, and quite untrustworthy when we are concerned with Palæozoic times. We must, indeed, admit that as the result of more searching criticism, and the increased knowledge of the facts which the labours of many years have now amassed for us, we are not in a position to answer that most important and fundamental question whether a continuous and universal cooling of terrestrial climate has or has not been progressing from the time of the earliest stratified deposits down to the present day.

The difficulties with which we have to contend in dealing with this problem may be illustrated by a very significant example. The fact has already been noticed that reef-building corals occur only in warm seas, in which, throughout the year, the surface-temperature never sinks below 20° C. If now we compare the geographical distribution of the reef-building corals of the older formations, we find in very early times, in Silurian and Carboniferous deposits, the remains of such corals beyond the Arctic circle; at a much later period in the Jurassic formation, we find that they reach only to North Germany and to Southern England; during the second half of the Cretaceous formation, they do not pass the northern limit of the Alps and the mountains of Southern France, and their northern limit in the first half of the Tertiary era is nearly the same. At the beginning of the second half of the Tertiary era, we find them but scantily represented on the northern boundary of the Alps, and abundant only in Southern Europe; and in the latest subdivisions of the Tertiaries, in Pliocene times, they have almost disappeared from Europe.

From these facts it might seem almost a manifest conclusion that there has been a continuous fall of temperature since Silurian times, in consequence of which reef-building corals have retrograded through some fifty degrees of latitude; nevertheless, on closer examination, we find that such an inference would be altogether premature. In the first place, the Palæozoic corals differ very essentially from those that now exist, and therefore their requirements in respect of warmth may have been totally different; further, we have no knowledge of any coral reefs in the far north in all the older formations; and between the Carboniferous and Jurassic formations which we have cited, there intervene the Permian and the Trias in which we know of no reef-building corals so far north; the most northerly representatives of the group in Permian times appear in North-Western India, those of Triassic times in the Alps. We are therefore absolutely ignorant whether these changes of distribution, supposing them to have depended on the temperature, are not to be ascribed to alterations in the distribution of temperature, while there may have been no continuous cooling. Lastly, it is by no means definitely ascertained that the position of the earth's axis has always been the same as at present; indeed, there are in the course of geological time certain definite epochs pointing to such a displacement of the poles, of which we have yet to gather the meaning. It may therefore be the case that those parts of the earth at which we find Silurian and Carboniferous corals in the neighbourhood of the pole, were much nearer the equator in those early times than they now are.

Similar difficulties present themselves in all our attempts to arrive at far-reaching conclusions by this method, and thus we are admonished how great caution must be exercised in the face of so many sources of error. Another method, by means of which it has been sought to attain some holding ground for determining the climatic characteristics of early times, is that, leaving out of consideration the conditions under which nearly related organic types exist at the present time, we should simply regard the extent of the geographic distribution of extinct organisms, and from their wide distribution conclude the existence of a uniform climate over very great areas, nay even over the entire globe. But in such an attempt the risk of over-estimating the facts is imminent, and especially is this true in the case of marine organisms; in a former state of our knowledge, we might well have believed that ancient forms of life had a wider distribution than such as now exist, since our knowledge of the tenants of the present seas related almost exclusively to those of shallow water and the coasts, many of which have a restricted range. But from the epoch-making deep-sea soundings of the last decennia, we have learned much of the inhabitants of the depths of the ocean, and have become aware that they possess much the same characters in all parts of the world; so that, in this respect, there is no essential difference between the present and former ages. As a fact, we have ascertained, from the distribution of organic life, that climatic zones existed in most of the early periods, and that this has not been done in some cases may be simply ascribed to the fact that they have not yet been rightly investigated.

Side by side with the diverse indications afforded us by the animal and vegetable worlds, regard must be had to the petrographic characters of the old deposits. We have rocks which have issued from the interior of the earth and have solidified from the fluid state, others have been deposited from water, and in the formation of others, again, ice has played an important part, and this mode of formation is generally recognizable by well-marked characters. For our present purpose, only such masses are important as have been transported by ice and thus brought to their present position, for these alone furnish us with conclusions as to temperature conditions; they inform us that, whenever they occur, the cold has been, at least at times, sufficiently great to freeze large masses of water.

The marks of ice action are well known. A moving glacier polishes and scores or scratches its rock floor, and carries with it fine silt, sand, great and small stones, and even mighty boulders, and deposits these materials in its moraine, without sifting them according to magnitude, as in the case of transport by water. Polished and grooved rock surfaces, scratched pebbles, and deposition without stratification in a confused mixture of silt, sand, coarse pebbles, and enormous blocks, are the indications of glacier deposits; in the identification of which, nevertheless, great caution is necessary. If a glacier reaches the sea or a great lake, under certain conditions, masses of ice may be floated away to great distances, carrying with them the enclosed stones and boulders, and often deposit them when thawed out of the iceberg, on the sea-bottom at great distances from their place of origin. Thus the deep-sea investigations of the *Challenger* show that, in high southern latitudes, in the deep sea and far from any coast, numerous stones lie scattered on the fine silt of the ocean-floor, and these can have reached their present position only by such means of transport. Such indications are, however, not quite undeceptive, since it sometimes happens that stones are transported in the roots of trees which are carried by rivers into the sea; but this kind of transport is operative only to a very small extent. When, however, we find in old formations water-formed deposits of fine clay or sand extending over great areas, in which numerous great stones and boulders are promiscuously intermingled, we may infer that they have been transported by floating ice, especially when the stones moreover are scored.

We have now learned what are the most important indications from which we may draw inferences as to the climatal conditions of past ages, and we have endeavoured to ascertain how far, and within what limits, such inferences are legitimate. Our next task will naturally be to apply the conclusions thus established to the phenomena which we meet with at different epochs of the past, and to form a conception of the climatic relations of those times, and of the conditions depending on them. It would, however, lead us too far afield were we to discuss each period in detail, and we must restrict ourselves to a

hasty sketch of a few especially important formations that have been closely studied.

We pass over the oldest deposits, for the interpretation of which but few points of vantage present themselves, and we shall fix our attention on the upper half of the Carboniferous formation, the so-called Coal-measures. It has received this name because in many countries it contains those thick beds of fossil fuel which have become an indispensable factor of modern industries, and without which the actual status of our social and political condition could not have been attained. So great is the quantity of the fuel herein stored, that all that is furnished by other geological formations, taken together, falls far short of it. There is much difference of opinion as to the mode in which coal has been formed; but whatever disagreement there may be in matters of detail, this much is certain, that we have in coal the altered remains of a land-vegetation, which, partly at least, flourished in swamps. Of course the formation is not all or even chiefly coal; even where it is richest in coal, by far the greater part of the formation consists of shale, sandstone, and conglomerate, and the coal-beds are here and there interstratified, forming but a fraction of the total thickness. We may picture to ourselves the building up of the formation by supposing that a plain or depression was sometimes covered with water, sometimes dried up. When flooded, chiefly with fresh and but rarely with sea-water, beds of shale or sandstone were deposited; when dry, land or swamp plants sprang up, and their decayed remains furnished the material of coal. Then followed another period of inundation, and thick beds of shale, sandstone, and conglomerate were again deposited. . . . .

The vegetation that in its decay formed our beds of coal was of a peculiar character. As yet there existed no trees (with true foliage) and no flowering plants. A monotonous growth of plants with stiff leaves then clothed our continents. A great part in it was played by *Calamites*, great plants which no longer exist, and whose nearest relatives are the mares' tails so often met with in marshy ground; another important type was that of the *Lepidodendra*, large trees whose forked stems were covered with leaf scars arranged in a regular geometrical pattern, and the branches of which were clothed with short, stiff, grass-like leaves; and most important of all, the *Sigillarias*, the unbranching and twigless stems of which were marked with leaf scars in perpendicular rows and scale-like leaves. Both of these are long since extinct; and only the insignificant club-mosses of our present flora recall to us the varied gigantic forms of that distant age.

H. F. B.

(*To be continued.*)

LIGHTNING AND THE ELECTRIC SPARK.[1]

AT a date at least as remote as 600 years B.C. the Greek philosophers were acquainted with a curious little fact to which the modern science of electricity owes its name. They knew that a piece of amber (ἤλεκτρον) when rubbed against some suitable substance acquired a temporary attractive power, in virtue of which it became capable of lifting and holding light objects, such as dry leaves or pieces of straw. But another remarkable effect which often attends the friction of amber was for many centuries altogether overlooked. In A.D. 1708 it was first noticed by Dr. Wall that a piece of strongly excited amber emitted sparks, which were accompanied by crackling sounds, and these he had the sagacity to compare to thunder and lightning.

It must be confessed that the recognition of any resemblance between the microscopic scintillations thus produced and the brilliant lightning flash imposed a somewhat severe strain upon even the scientific imagination, and a few years later Stephen Gray, in reference to the same comparison, expressed the hope that "there might be found out a way to collect a greater quantity of the electric fire" than was then possible. His hope was realized by the subsequent improvement of electrical apparatus, and especially by the invention of the Leyden jar; and the effects obtainable by the means now at our command amply justify the speculations of Wall and Gray. The essential identity of the artificial electric spark with the natural lightning flash was conclusively established by the experiments of Franklin, and in these days it has become a mere common-place, familiar to everyone.

There are generally said to be two kinds of lightning flash, which are known as forked lightning and sheet lightning, the former being dangerous and destructive, the latter harmless. To these is sometimes added a third class, called ball lightning. The lightning flash of artists which is familiar to us from innumerable pictures, and of which the venomous-looking zigzag now projected upon the screen (copied from an engraving) is a fair example, has no existence in nature. It is simply an artistic fiction or symbol, like the conventional representation of a galloping horse, which, in the severe language of Mr. Muybridge, resembles nothing to be found in the heavens above or in the earth beneath. The absurdities commonly perpetrated in depicting animals in motion have been fully exposed by Mr. Muybridge with the assistance of photography. So, too, it is photography that has given the *coup de grâce* to the traditional forked lightning. Within the last few years an immense number of photographs of lightning flashes have been made. The Meteorological Society has formed a collection of these, containing about 200 examples, which, by the kindness of Mr. Marriott, the Secretary of the Society, I have had an opportunity of examining carefully. Not a single instance of the artistic lightning flash is to be found among them. The great majority bear a close resemblance to the sparks of our electrical machines: a few are distinguished by peculiarities which, though at first sight a little difficult to account for, can generally be explained and even imitated artificially.

What may be called a typical lightning flash is a stream of light which follows a sinuous and wavering course, very like that of a river as shown upon a map. [Several photographs of this kind of flash were exhibited by means of the lantern.] The next slide is a photograph of a machine-spark, about 3½ inches in length. The two kinds of discharge are so much alike in their general character that if it were not for the surroundings it would be hard to tell which was the lightning and which the artificial spark.

The variations upon the normal type of flash, which the Meteorological Society's photographs show, have been classified as ramified or branched lightning, beaded lightning, meandering or knotted lightning, ribbon lightning, and, lastly, dark lightning.

Branched lightning is again strikingly suggestive of a river in a map; not a simple stream, however, but one into which a number of tributaries flow. [Photographs were shown.] Sparks having branches of just the same character are easily produced by a large electrical machine. To obtain the effect well, the negative terminal should be made much larger than the positive, and the two should be separated so far that a spark will only just pass between them. According to Faraday, a ramified, or as he sometimes calls it a "brushy," spark occurs when the whole of the electricity has not been discharged, but only portions of it, more or less, according to circumstances. It is a "dilute" spark, generally passing to air or other badly conducting matter ("Exp. Res.," § 1448). When therefore a ramified flash occurs we may reason-

[1] Extracted from a lecture on "Electrical Phenomena in Nature," delivered by Mr. Shelford Bidwell, F.R.S., at the London Institution on February 10, 1890.

ably conclude that the discharge is partial and incomplete.

In beaded lightning there occur a number of bright spots, giving the flash the appearance of an irregular string of lustrous beads. This phenomenon is sometimes well shown in photographs of the machine spark, especially when the quantity of electricity passing is increased by using very large Leyden jars. Under these circumstances the path of the discharge is often found to contain at irregular intervals certain small and abrupt V-shaped indentations, and these, especially when seen "end-on," appear to be more luminous than other portions of the flash. Probably, therefore, in a beaded flash the quantity of electricity passing is more than ordinarily great.

Sometimes a lightning flash appears to take a very circuitous and roundabout path, perhaps forming a nearly closed loop, or even a complete knot. Such is what the Thunderstorm Committee of the Meteorological Society have called "meandering" lightning. This remarkable effect is no doubt the result of an optical illusion, and occurs when the general direction of the flash (or of part of it) is either towards or away from the observer.

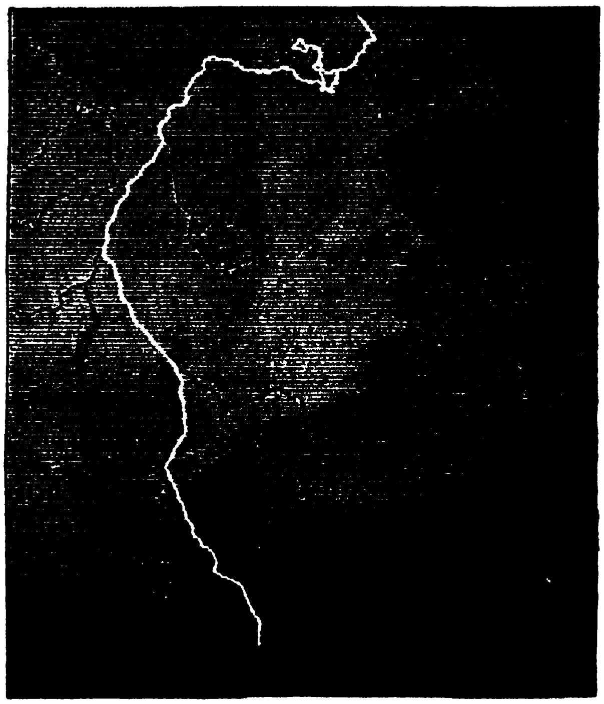

FIG. 1.

The different parts of the flash which seem to approach or to cross one another may in fact be miles apart. This explanation may be simply illustrated by means of the shadow of a properly bent wire. I have here a wire which is bent in such a form as to imitate a common type of flash or machine spark. When held transversely to the beam of the electric light its shadow is seen to represent fairly well the form of an ordinary sinuous flash; but if it is turned round so that its length is in the direction of the beam of light, the shadow presents an intricate appearance of loops and knots. Fig. 1 is from one of the most remarkable photographs of lightning flashes that I have seen. It was taken at Cambridge on June 6, 1889, by Mr. Rose, of Emmanuel College, and I am indebted for this copy to the kindness of Mr. W. N. Shaw, who described it at a recent meeting of the Physical Society. Among its many interesting features I will at present only direct your attention to the complicated knot which occurs in the upper part of the flash.

Many photographs of lightning have a curious flat and ribbon-like appearance. Such ribbons are sometimes broad and sometimes narrow. I have to thank Mr. Clayden for an excellent specimen of the broad kind, which was taken by himself last summer, and is reproduced in Fig. 2. The Thunderstorm Committee are of opinion that this peculiar structure may possibly not exist in nature at all, the effect being produced only in the photographic camera. It is noteworthy that, in nearly if not quite every case when broad ribbons have been obtained, the camera was held in the operator's hand, a fact which naturally suggests the idea that the widened image of the flash may be due to unsteadiness. It may be objected to this explanation that the duration of a lightning flash is so exceedingly brief as to preclude the possibility of any material movement during the time that its image is upon the sensitive plate. But such an objection is not unanswerable. It has often been observed that a lightning flash may be followed by one or more other flashes in rapid succession, all taking precisely the same path as the first. If then the camera were in motion a series of such flashes might impress themselves side by side upon the photographic plate, being so near together as to give the appearance of a single wide and flattened flash.[1] Moreover, though the true lightning flash is practically instantaneous it sometimes has a phosphorescent glow along its track, which lasts for at least a large fraction of a second. This phosphorescence would tend

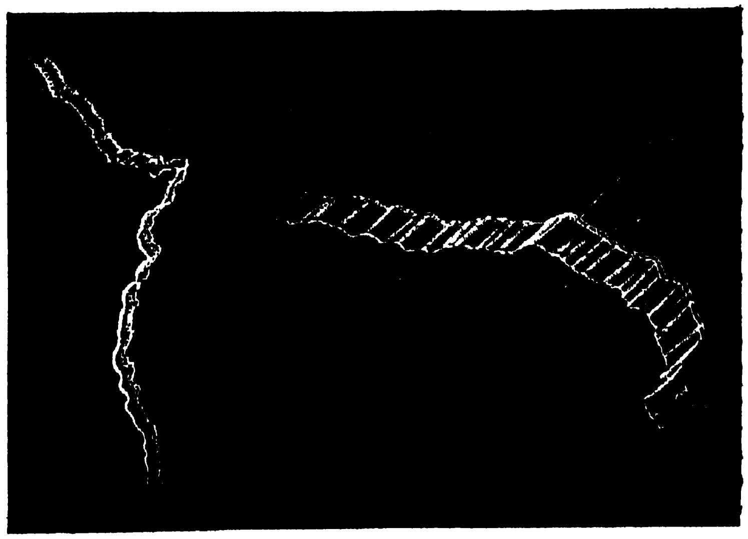

FIG. 2.

to connect the separate images into a uniform whole, and add to the ribbon-like appearance of the resulting picture. Dr. Hoffert has been kind enough to give me a copy of an exceptionally interesting photograph[2] which illustrates this explanation. The camera was held in the hand, and moved horizontally to and fro at the rate of about once in three-quarters of a second. The movement was continued until a flash was observed, when the lens was at once covered. The plate after development showed no less than two triple flashes and one double flash, eight in all, the whole of which, must have occurred, Dr. Hoffert thinks, within a little more than a second, forming a connected system of discharges which would appear to the eye as one. The several sets of flashes in the photograph are all joined together more or less perfectly by horizontal luminous streaks, which, though they may not impossibly represent a continuous brush-like discharge, are more probably due to phosphorescence of the oxygen of the air, oxygen, especially in the form of ozone, being a phosphorescent substance. If in taking Dr. Hoffert's photograph the camera had been moved

[1] It has been pointed out by Prof. S. P. Thompson that the path of the discharges might be shifted by the wind to a sufficient extent to produce the ribbon-like effect, even if the camera were perfectly steady.

[2] A good reproduction of this photograph is given in the *Phil. Mag.* (1889), and in the Proceedings of the Phys. Soc., vol. x. p. 176.

slowly instead of quickly, I think it is clear that the appearance of one or more ribbon-like flashes, like those in Fig. 2, would have been produced.

But the photograph of a flash may possibly assume a distinctly broadened form, perhaps more suggestive of a flattened wire than of a ribbon, when the camera is absolutely steady. In such cases it will generally (perhaps always) be seen that one edge of the image is sharp and clear, while the other is ill-defined and hazy. I have succeeded in imitating this effect very well in photographs of the machine spark: it is obtained when the light does not fall perpendicularly, or nearly so, upon the sensitive plate, and is no doubt due to successive reflections between the surfaces of the lens. [Exhibited.]

Lastly, we have to consider the so-called "dark flash." It occasionally happens that, on developing a photographic plate which has been exposed during a thunderstorm, the image of a lightning flash comes out black instead of white. Fig. 1 presents a striking instance of this phenomenon. Black ramifications are seen to proceed outwards on both sides of the main bright flash; there is also what appears to be an independent black flash which starts from the top of the picture and crosses the bright one near the knot. The origin of this strange appearance was for a long time a mystery. No one had ever seen a dark flash with the unassisted eye, and the question arose, whether the dark images in the photographs really represented a hitherto unobserved physical effect which occurred in the air itself, or whether, owing to some optical or chemical action taking place inside the camera or upon the sensitive plate, the impression of a luminous flash became converted into a dark one. There is no need to discuss the several ingenious hypotheses which were suggested in explanation of the anomaly; it is sufficient to say that the mystery was completely cleared up a few months ago by the experiments of Mr. Clayden. The fact, as demonstrated by him, is shortly this. If the lens of the camera be covered the moment after a flash has occurred, the developed image will always come out bright, feebly or strongly according to circumstances. If, however, the plate be exposed after a flash has acted upon it, either to the continued action of a feeble diffused light or to the powerful glare arising from one or more subsequent flashes, then on development the image of the original flash will probably come out black. The effect is therefore not a meteorological or physical one, but purely chemical. It can be obtained not only with a lightning flash, but also with a machine spark, or even with an ordinary flame. It is merely necessary that the plate should be exposed to the action of a certain amount of light after it has received the impression and before development.

Some photographs which I have made of machine sparks fully confirm this explanation of Mr. Clayden's. The room was illuminated by a single gas-jet, and the background was a white screen with a black post in the middle of it (see Fig. 3). Two series of sparks were passed between the ball terminals of an electrical machine and photographed. After the first series were taken, the lens was left uncovered for half a minute; then it was capped, the camera shifted slightly, and the second series taken; the lens was again left open for half a minute, and the plate afterwards removed from the camera and developed. It will be seen that while the second series of sparks come out bright in the natural way, the first series have been reversed and blackened by the action for one minute of the light reflected from the white screen upon the undeveloped image. Exposure to the diffused light for half a minute only was not in this case sufficient to cause reversal.

These experimental results make it almost certain that the flash in Fig. 1 was really a double one. The first flash was comparatively feeble, and possessed the lateral ramifications characteristic of an incomplete discharge. The second, which probably occurred immediately afterwards, was a powerful one without ramifications, and followed accurately the main path traced out by the other. The glare arising from this second discharge caused the photographic reversal of the ramifications belonging to the first.

Everyone must have noticed the proverbial quiver of a lightning flash. This peculiar effect is often due to the multiple discharge of which we have already spoken. Sometimes, however, I believe the phenomenon is a purely subjective one, depending upon a certain physiological reaction of the optic nerve. If we gaze at a bright flame which is suddenly uncovered and immediately extinguished, then after a very short interval of darkness a distinct but transient image of the flame will reappear; and it is even possible that after another brief interval a second after-image of the flame may be seen. It is, however, by no means easy to detect these appearances without considerable practice, because they belong to a class of impressions which we habitually train ourselves to disregard. But by means of a little device which I published a few years ago, the phenomenon may be easily demonstrated to almost anyone.

The beautiful effects produced by the rotation of a vacuum tube when illuminated by a series of discharges

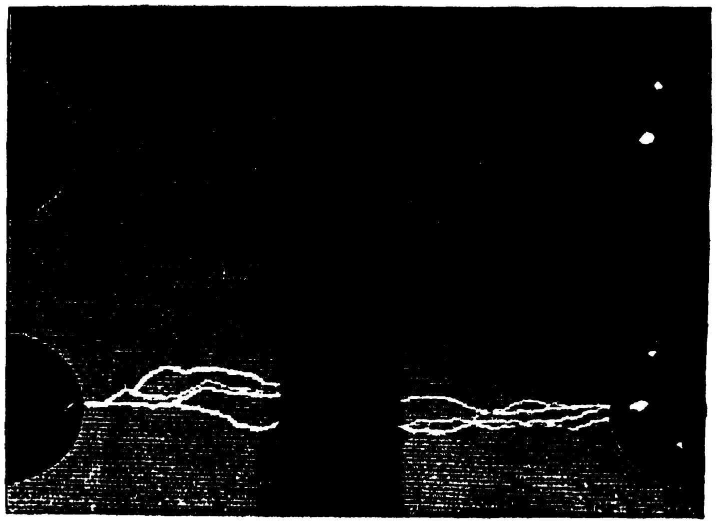

FIG.

from an induction coil, are well known. The tube is generally attached to a horizontal axis, which is turned rapidly by means of a multiplying wheel; the images due to successive discharges, which, if the tube were at rest would be superposed, are thus caused to occupy different parts of the retina, and the result is the appearance of a gorgeous revolving star. But if the tube is caused to rotate very slowly, making about one turn in two or three seconds, there occurs a different and very curious phenomenon. The luminous images of the tube are almost superposed, forming a bunch which is slightly spread out at the ends. But about 40° behind the bunch, and separated from it by an interval of darkness, comes a ghost. This ghost is in shape and size an exact reproduction of the tube; it is very clearly defined, and is of a uniform bluish-grey tint. If the rotation is stopped, the ghost still moves slowly on, and after the lapse of about half a second disappears in coalescing with the luminous tube. The phenomenon of the ghost is clearly due to a succession of after-images, which are perceived a short time after the retina has been impressed by the flashes from the vacuum tube; and a similar physiological action, I think, explains—at least in some cases—the apparent reduplication of a flash of lightning.

Within the last year or two there has been a great deal of rather lively controversy concerning the protection of

buildings from the destructive effects of lightning. The controversy originated in some lectures on lightning conductors, delivered by Prof. Oliver Lodge at the Society of Arts in 1888; it was continued at the Bath meeting of the British Association, and it culminated in a paper, also by Dr. Lodge, read last year at the Institution of Electrical Engineers, in which, after stating that "the old views on the subject of electrical conduction are hopelessly and absurdly and dangerously inadequate," the author expressed the opinion that it was "time that the prophets of the old superstition were slaughtered by the brook Kishon." In the animated discussion which followed, Dr. Lodge's views were ably opposed by Mr. Preece and others, and the question can hardly yet be considered as definitely settled. Time will not admit of an adequate review of the arguments which were employed on the two sides, but, considering its great practical importance, I think it will be of interest to give a very short statement of the matter in dispute, which I will illustrate by copies of Dr. Lodge's diagrams and apparatus.

Ever since the time of Franklin it has been customary to make use of long pointed metallic rods for the purpose of protecting important buildings from damage by lightning; and the "older electricians," as Dr. Lodge calls them, have always taught that, if the rod were well made, of sufficient size and height, and properly connected to earth, it afforded practically perfect security over a certain limited area. The function of the rod was supposed to be not so much to receive the shock of a lightning flash as to prevent a flash from occurring at all in the neighbourhood of the protected building: this it did by promoting the silent discharge of electricity between the cloud and the earth through the point of the rod.

The lower of these two tinfoil-covered boards represents the earth, and the upper one a cloud; the upright metal rod with a ball at the top of it is supposed to be a church, or other building, erected upon the earth. Charging the apparatus by means of the electrical machine, we get a series of strong flashes between the cloud and the church, every one of which might do terrible damage. If now we place near the church another rod, with a needle-point at its end, to serve as a lightning-conductor, the flashes at once cease: however vigorously we work the machine, there is no longer any visible effect. The fact is, that the electricity is silently and harmlessly discharged as quickly as it is generated. In such a case as is at present represented by the model, the efficacy of a lightning conductor would be complete. This is what Dr. Lodge calls the case of "steady strain," and is that indicated in his first diagram [exhibited], where the charged cloud above the church spire is supposed to have moved into its present threatening position from a distance. According to Dr. Lodge, this is the only kind of lightning discharge which was ever contemplated by the older electricians.

But suppose that a harmless uncharged cloud which might be hovering over the church were suddenly to receive an overflowing charge of electricity by a flash from another more distant cloud. There would then be no time for any gradual relief of the strain by a silent discharge through the lightning conductor, and either the conductor itself or the church would infallibly be struck by a flash from the overflowing cloud.

By altering the connections between the model and the electrical machine,[1] we can easily imitate this condition of things. The tinfoil-covered boards now remain absolutely uncharged until the moment when there is a spark between the terminals of the machine: then they are suddenly charged, and a flash instantly passes between the cloud and the church. Placing the needle-pointed lightning conductor beside the church, we now find that it is powerless to prevent the flashes: they go on just as rapidly as before, striking either the conductor or the church, or sometimes both at once. This case, which, I think, Dr. Lodge was undoubtedly the first to call attention to explicitly in connection with thunderstorms, is called by him the case of "impulsive rush." The occurrence of an "impulsive-rush" flash, then, cannot be warded off by a lightning conductor. The most that a conductor can do is to divert the main shock of the discharge from the building to itself. But even so the lightning may do considerable damage, for, as Dr. Lodge says, "it is hopeless to pretend to be able to make the lightning conductor so much the easiest path that all others are protected. All possible paths will share the discharge between them, and lots of apparently impossible ones." Moreover, not only is the lightning conductor itself, when struck, liable to spit off sparks laterally, however good its earth connection may be, but other metallic bodies in the neighbourhood may do the same, whether such bodies are insulated or not.

The moral appears to be this. In all cases of steady strain in which a charged cloud descending from the upper regions of the air, or approaching from a distance, might inflict serious injury upon an unprotected building, a well-designed and properly earth-connected lightning-rod is an absolute safeguard. In a case of "impulsive rush," the rod may often be of use in bearing the brunt of the discharge, though sometimes the lightning will take no notice whatever of it, striking the building and altogether neglecting the rod; and it is even possible that a high rod might attract a destructive discharge which otherwise would not have occurred at all. Although, therefore, a lightning-rod is in many cases, probably in a very large majority, of the greatest service, it cannot be depended upon as affording perfect immunity from risk; and the assumption which has universally been made by the "older electricians," that damage by lightning is in itself conclusive evidence of some imperfection in the conductor, is an unfounded one.

In conclusion, it may not be out of place to say a word or two on the subject of personal danger from lightning. The spectacle of a severe thunderstorm, magnificent as it is, is no doubt calculated to inspire a certain amount of alarm. But statistics show clearly enough that, at least in this country, its bark is worse than its bite. It appears, from a paper published last year by Inspector-General Lawson, that the number of deaths caused by lightning in England and Wales from 1852 to 1880, as recorded in the returns of the Registrar-General, were 546, or rather less than 19 per annum. The average population during that period may be taken as 22 millions; it follows, therefore, that the average annual death-rate from lightning was considerably below 1 per million of the population. The risk of a fatal lightning stroke in any individual case is therefore exceedingly small.

[1] The tinfoil-covered boards were connected with the outer coatings of the Leyden jars, their inner coatings being in connection with the terminals of the machine.

SPORTS.[1]

It is highly desirable that we should attach a definite signification to this word. Among gardeners it may mean many things, whilst, among botanists, it is restricted to cases of bud-variation as distinguished from variation from seed. In this note we shall use the word in its botanical sense, as applying to a special illustration of that tendency to vary which is common to all living beings. We shall, however, gain a clearer idea of what true sports are by the elimination of certain things which are not sports, though often called so. In the first place they are not seedling variations. Out of a hundred seeds of Lawson's Cypress that are sown it is possible, I suppose,

[1] Reprinted from *Garden and Forest*. The article contains the substance of an unwritten address lately given to a society of gardeners.

to get ten more or less distinct varieties, besides others which are more or less indistinct. The great variability of this species is now well known, and the seedlings of *Abies subalpina*, Engelmann (*A. lasiocarpa* of Hooker), furnish another illustration of the same tendency. These seedlings may be the result of cross-fertilization between varieties, or they may be reversions to an earlier condition; at any rate, of whatever nature they are, they are not "sports" in the sense here intended.

Next, sports are not mere stages of growth. Most plants put on a different appearance at various periods or stages of their growth, and sometimes these changes are very remarkable. The Retinosporas of our gardens furnish us with excellent illustrations. *Retinospora* (or more strictly *Thuya*) *pisifera* exhibits during its growth very different appearances in its foliage. There is the squarrose form and the plumose form, the golden form, the silver form, the pendulous form, the thread-like form, the upright form, and perhaps others. All these, however, are not separate entities; they may all occur on the same bush. If cuttings or if grafts be taken from the sporting branches they may be reproduced almost indefinitely.

Barring the mere colour variation, these forms are but stages in the growth of the plant, occurring with more or less regularity and in greater or less degree of prominence in all the individuals of the species, as may be inferred from watching the growth of seedlings in a seed-bed.

Other illustrations of variations arising during growth are afforded by the differences often observable in the foliage on the flowering branches as contrasted with that on those branches which bear no flowers. The common Ivy furnishes an illustration. The short contracted shoots of the Laburnum, or the Apple, known as "fruit spurs," constitute other examples.

Another form of variation in flowers is that connected with difference of sex. A "pin-eyed" Primrose does not greatly differ in appearance from a "thrum-eyed" one, yet the difference between them is precisely of the same character as that between the variously formed flowers of some species of Catasetum and Mormodes. So utterly different are the male and female flowers of some of these species that they were at first placed by very competent botanists in different genera. It was only when the Protean plants produced all the forms of flowers on one and the same spike, that it was seen that, so far from belonging to different genera, they did not even belong to different species. It was left to Darwin to show what this paradoxical variation really means; and now, when we meet with a case of the kind, we say, "Ah! yes; only a sexual form," just as if we had known all about it from our earliest years, and very possibly, in our haste, mixing up, or, at least, not discriminating cases of a different nature. But this is not what we propose to discuss just now; we simply say that these cases, though often so designated, are not sports, at least in our acceptation of the term.

What, then, are sports? We have already characterized them as "bud-variations," but we must give some further indication of their peculiarities: First, as to the suddenness of their production. A tree or a shrub, all on a sudden and without any cause that is apparent to the eye, will put forth a bud, which, as it lengthens into a shoot, displays leaves of a different character from any that the plant has hitherto produced, which have no definite relation to any particular stage of growth; and which are quite different from any that under ordinary circumstances the plant in question has produced or is likely to produce in future. In short, the occurrence is sudden and unforeseen. Gardeners, of course, avail themselves of these variations. They remove them, bud them, graft them, strike them from cuttings, or, in some way or another, endeavour to perpetuate the variety, and thus have originated many of our cut-leaved Beeches, Maples, and Limes. Thus, too, may have originated some of our weeping trees and some of our pyramidal shrubs, though, for the most part, these have, as I believe, originated as seedling variations.

Not only do these variations occur suddenly, but they are very local in their manifestation. One particular shoot "sports," while all the rest remain in their normal condition. It is very different in the case of seedling varieties, where the whole system of branches and leaves is more or less affected.

Another and a most remarkable feature about these sports is, that they sometimes occur simultaneously in widely different localities; thus the same sport of a Chrysanthemum "turns up" about the same time, not only in different nurseries in this country, but also on the Continent. This may be because all the plants in question have originated from one and the same stock.

These, then, are the special characteristics of a true sport. Illustrations could be given by the hundred; but neither time nor space permit, nor, indeed, for our present purpose, is it requisite to do so. Whoever will investigate the cause of these sudden outbursts of local variation must, of course, sedulously examine each case for himself according to the measure of his ability and of his opportunity. The circumstances, the history, the progress, the anatomy of each particular sport must be investigated, both absolutely and in relation to similar outgrowths in other plants. Until this is done—and it has not been done yet—any explanation as to the cause of the phenomenon must be a matter of speculation. Still, we cannot help guessing, and though we may be wrong in our surmises, at least the process does good by setting us observing and thinking. Observing and thinking are processes valuable to all of us, but in a particular degree to those who practice the cultural arts. And so it happens —or, at least, we will hope so—that although the causes which have been assigned for these changes are various, some, perhaps, utterly wrong, others partially so, and all more or less inadequate to explain the whole of the phenomena, yet some advantage may accrue from the discussion. An indirect benefit is better than none at all, and anything which enforces us to take some measure of the extent of our own ignorance is likely to be beneficial. We should never be a bit the better if we simply acknowledged our ignorance, as, indeed, we needs must do in any case, but directly we attempt to find out in what particulars and in what degree we are ignorant, then there is some hope that some portion of our "nescience" may be dispelled. Under this impression we may allude to one or two of the assigned causes of sporting. External causes are those which the gardener most generally invokes. For him a sport is usually the consequence of some alteration in the nutrition of the plant. It gets too much or too little food, or the food is not of a suitable character—containing too much of one thing, too little of another, or the climate is charged with the results observed. It is very convenient to have the weather to blame; it may be too hot or too cold, too moist or too dry, too brilliant or too obscure; or the soil may be at fault, the drainage may be defective, the earth not sufficiently aërated, its temperature too high or too low. Combined action of some of these conditions is, of course, possible, intermittent action equally so, whilst we, in this country, are abundantly familiar, first with one thing in the way of the weather, and immediately afterward with another. It is, therefore, not surprising if some gardeners, without troubling themselves much to see how the explanation fits the facts, do attribute "sports" to such causes as we have mentioned. To our thinking, the objections to this kind of explanation are fatal. External circumstances are, no doubt, potent enough to effect very great changes indeed. We are daily witnesses of them; but they do not produce the kind of change which we know as "sports." On the contrary, sports occur some-

times when no alteration of external conditions is perceptible, and they do not occur when such alterations are very apparent. Or, again, they appear in one place under one set of circumstances, and at another place, simultaneously, under a different state of affairs; and although all the plants growing together have been exposed to the changed conditions of life, the sporting tendency shows itself in one particular plant only, and in one particular part of that plant, generally only in one bud. With all respect, then, for those who hold these views—and one at least of our most experienced and eminent plant-growers has lately publicly advocated them—we venture to think external causes, however adequate they may be in some cases, are inoperative in such cases as we are considering.

A better explanation is that offered by Darwin, by Naudin and others, according to which sports are due to a dissociation of mixed elements, a reversion to the character possessed by one or other of the ancestors of the plant, perhaps one or two, perhaps an indefinite number of generations ago. Let us recall for a moment what a very composite thing a plant is, even such a one as we call a simple plant. At first it is neutral and homogeneous, a mass of protoplasm, but the homogeneity of protoplasm is a thing of the past. We do not believe in it now. On the contrary, we believe in frameworks and interstitial fluid, in granules and fibres, in some parts that are alive, others that are dead; some that are stable and immutable, others that are mobile and changeable; in short, we have come to the conclusion that, physically and mechanically, as it was previously known to be chemically, protoplasm is very much "mixed."

Again, another of our old beliefs has been dissipated. Once we were taught that the cells of plants were closed bags without apertures, and that, while the fluid passed from cell to cell by osmosis, there were no visible pores, and no means of transmitting anything more solid than cell-sap. The passage of protoplasm from cell to cell was not then thought of as possible. But Mr. Walter Gardiner has changed all that. He and others who have followed in his steps have taught us how to see the pores in the cell-walls, how to see the passage of protoplasm through those pores from cell to cell, and how complacently to employ the phrase "continuity of protoplasm" in a manner that gives us, at present at least, great satisfaction. These modern discoveries of the composite nature of protoplasm, and of its passage, at certain times and under certain conditions, from cell to cell, seem to us to furnish a clue to the explanation of some of these cases of sporting, as they do also in the case of some of those curious cases in which the stock seems to influence the scion, or the scion the stock, in cases of grafting.

Again, in the life-history of a plant there are several stages. There is the neutral stage, when it is, at any rate, so far as sex is concerned, an epicene. Then there is the sperm stage, when our plant consists of a mass of neutral matter, a particular portion of which is developed into sperm-cells, or into what will ultimately produce them. At another time the neutral cells of one portion of the general plant-mass develop into germ or female cells, or it may happen that both sperm and germ cells may be developed at one and the same time, when the plant has, of course, a three-fold constitution.

All these modifications occur in the course of the life of each individual plant. But each individual plant is, necessarily, compounded of elements derived from its two parents, so that, for illustration sake, if we may consider the original stock to consist of three portions—neutral, male, and female, respectively—it is obvious that in the first generation there would be six component elements; in the second, twelve; in the third, twenty-four, and so on. Who can count the generations of plants? It is enough for our purpose if we succeed in showing clearly the composite nature of plants.

This being granted, it will not seem remarkable that occasionally a partial separation takes place, just as a scum may rise to the surface of some mixed fluid, or a sediment fall to the bottom of another. This illustration may, perhaps, serve to suggest the reason for the separation of mixed elements in plants; but that is too speculative a matter for us to enter upon here. It will be better for our present purpose to note one or two examples of dissociation of mixed characters wherein both the fact and its explanation are clear. One of the most interesting is that narrated by Mr. Noble, the originator of the white form of Jackman's Clematis. Noble's Clematis, as we may here shortly call it, is the result of a cross between Jackman's Clematis and *C. patens*. Soon after this Clematis was sent out, some dissatisfaction arose because, instead of producing flowers of good form and purity of colouring, more or less misshapen blooms of an unattractive appearance were formed. The matter was mysterious. The raiser was blamed by those who did not know that he is a highly competent man in his business, and one whose integrity is beyond question. The plant was condemned. Fortunately, however, the edict was not carried out in its entirety—some specimens were left. These were watched, and in due time afforded the explanation of the mystery. Jackman's Clematis flowers in the autumn on shoots formed during the spring and summer—on the new wood, as gardeners say, just as happens with a Rose. *Clematis patens* flowers in spring on shoots that were formed during the previous summer, on the "old wood," in gardening phrase. Now, when Noble's Clematis came to be scrutinized, it was found that it produced two kinds of flowers. Those which expand in spring are solitary, semi-double, never white, but bluish-gray, like those of *C. patens*. Those which unfold in autumn are produced in pairs and are single, like those of *C. Jackmanni*, but white. In the spring no flowers of the Jackman type are ever seen, and when the old wood is cut away, and only new wood thus suffered to produce flowers, no blooms of the *patens* character are seen, but only those of the Jackman type.

Another very interesting case of unmixing, or, if it be preferred, of partial mixture, is afforded by Neubert's Berberis. This is a hybrid between the evergreen pinnate-leaved Mahonia and the deciduous simple-leaved *Berberis vulgaris*, and it bears leaves some of which are intermediate in appearance, while others are like those of one or of the other of its parents.

The two illustrations above given are instances of the results of cross-fertilization, in which the whole process has, so to speak, taken place under our own eyes. But for how many centuries has the Chrysanthemum, we will say, been crossed and recrossed and crossed again? This process of crossing seems destined to come to an end, because the flowers, after a time, become sterile, owing to the fact that the stamens and pistils, one or both, are imperfectly or not at all developed. Seedling variations in such cases must become more and more rare as the process of sterilization becomes more and more marked. If new seedlings are desired, raisers will have to go back to less highly modified flowers—to flowers, that is, which are more nearly in their original condition. But although the production of varieties in the Chrysanthemum by fertilization is thus limited, the development of sports by bud-variation may, and probably will, still go on, to the delight of the grower and the interest of the student. It must, however, be said that at least in the case of the Chrysanthemum the change is sometimes very slight, depending solely on the presence of colouring matter in some cases and on its absence in others. The form of the flower and of the foliage in many of these Chrysanthemum sports is in no wise different from that of the parent plant. This is only an illustration of the fact that all degrees of combination or of dissociation, as the case may be, may be expected to occur.

Is there any commingling of the elements of stock and of scion in the case of grafts? Botanists and gardeners, almost without exception, have asserted that there is none. Place on a sheet of wet blotting-paper, which may represent the stock, a drier piece of the same substance, which may represent the graft, and there will be a passage of the fluid from the lower to the upper paper, but there will be no mixture of the constituents of the two.

We have always wondered, if there were no reciprocal influence of stock on scion, why grafting is practiced at all, because we cannot understand the acknowledged advantages of the practice except upon the supposition of some modification being exerted. Gardeners triumphantly, as they were quite justified in doing, pointed to the millions upon millions of cases where no such modifications are visible. Botanists pointed to the closed cells from whose cavities only the thinnest of liquids could exude and permeate through the walls of adjoining cells. This was before the days of "continuity of protoplasm," as above mentioned. Now that we know that not only water, but protoplasm itself, may, under certain circumstances, pass from cell to cell, the difficulties in the way of conceiving that any influence could be exerted on the scion by the stock, or *vice versâ*, are very materially lessened, if not entirely removed.

But before the time we speak of, there were some alleged facts which, provided the history given were true, could only be explained on the supposition of the commingling of elements by grafting and subsequent separation. In other words, the possibility of graft-hybridization must be assumed. Whether it has been proved is another matter.

One of the strongest cases in its favour that we know of is that of the famous Adams's Laburnum (*Cytisus Adami*). We cannot go into detail as to the history of this extraordinary tree. It must suffice to say, that it is stated to have originated from the implantation of a bud of the dwarf, shrubby, lilac-flowered *Cytisus purpureus* on to the common Laburnum. Be this as it may, we have in our gardens on this side of the Atlantic trees which every year astonish the beholder by producing, together with the foliage and flowers of the Laburnum, tufts of *Cytisus purpureus* and all sorts of intermediate conditions between the two. If the stock exerted no influence on the scion, the buds should be pure *Cytisus purpureus* and pure *C. Laburnum*, without any intermediate forms. It would lead me too far to give other illustrations of the production of shoots of an intermediate character between stock and scion. Many such are on record, and many have come under my own notice. It must suffice for me to show that whilst we may, with a very great amount of probability, attribute the existence of some sports to the "un-mixing" of elements blended by means of cross-fertilization, whether between species (hybrids) or between varieties (cross-breds), we may, likewise, but with a less degree of probability, attribute the existence of others to a similar dissociation in the case of grafted plants.

Obviously the latter cases must be much less numerous than the former, and are purely artificial productions, not likely to occur in Nature.

Other assigned causes appear to me to pertain rather to variation in general than to that limited, localized form of it which is here considered as bud-variation, and may be here passed with the mere mention.

MAXWELL T. MASTERS.

A NEW SCIENTIFIC SERIAL.[1]

THE imposing series of four octavo volumes before us is the embodiment of the first five years' work in the new Museum of the Austrian capital. Of the nature and plan of the building itself our readers have already been made aware; the collections housed within it are rich in types and specimens of priceless value, and its affairs are administered by a large and efficient staff of specialists, many of whom have attained a world-wide reputation. The directorship lies in the hands of Dr. Franz Ritter von Hauer.

Each of these volumes consists of four parts, and embraces one year's work. The parts are issued quarterly, their limitation in size being determined by the progress of work in hand. The first part of the first volume, issued early in the year 1886, is exclusively a "Jahresbericht" for the preceding year. It has already received notice in our pages (NATURE, vol. xxxiii. p. 424). While for the most part a report of work done, it contains information concerning the Museum itself, together with a list of names of the officers and staff, and of the various donors, correspondents, and persons who studied in the Museum during the year, as of those to whom material had been lent, together with references to published works in the production of which the resources of the Museum had been utilized. Of the remaining fifteen parts, each contains one or more special treatises, together with "notices" of a miscellaneous character, correspondence, personalia, and administrative detail, with acknowledgments of acquisitions. The four volumes make up a total of over 1900 pages of closely printed matter, with 80 plates and numerous woodcuts. The illustrations are, for the most part, highly satisfactory; we would, however, have preferred the substitution of ordinary lithographs for the photographs of Ophiurids described in vol. ii.; the latter are too indefinite and unsatisfactory. Excluding the notices and miscellanea, which monopolize collectively 22 per cent. (415 pp.) of the printed sheets, there remain 1532 pages of a more solid nature, which make up the bulk of the collective volumes. These bear, in all, 55 treatises; some of them, as our pages have already borne testimony (NATURE, vol. xxxv. p. 204), are lists of types and specimens in the Museum, others are elaborate monographs dealing with highly involved structural detail. The Museum is divided into five departments, each having its own working staff, and the published works bear the following ratio: zoology, 23; mineralogy with petrography, 13; geology with palæontology, 9; botany, 7; anthropology and ethnology, 3. As might be expected from this list, many new species of organic beings have been described. We find much to admire in some of the monographs; and especial attention is demanded by those devoted to the ethnology of the South Sea Islanders, by Dr. Otto Finsch, and to the artistic products of the Dyaks, by Prof. Alois Raimond Hein. These memoirs extend over the greater portion (240 pp.) of an average volume, and they are amply illustrated; the information contained in them is of inestimable value, the illustrations are of rare merit, and it would be difficult indeed to surpass the coloured representations of Papuan handiwork which adorn the pages of Dr. Finsch's important communication. These monographs are based upon the collections in the Vienna Museum, and upon perusal of them we know not upon which of their acquisitions most to congratulate our Austrian *confrères*—those of types of Nature's productions, or those of objects of human artifice. Moreover, the appearance of the memoirs cited, now that the South Sea Islanders are receiving renewed attention, is most timely; and their value is greatly increased by the fact that the peoples to whom they relate are becoming demoralized and demolished by the advance of "civilization."

The Museum whence these *Annalen* emanate was opened to the public in August 1889 by "His Apostolic Majesty the Emperor"; and an account of the ceremony, with its attendant honours, is to be found in vol. iv. The pages of the journal show the custodians of the institution to be fully alive to the value of their charge. The

[1] "Annalen der k.k. Naturhistorischen Hofmuseums, Wien." Bd. I.-IV. 1886-89. (Wien, Alf. Hölder.)

journal itself not only serves them as a catalogue, but as a medium for publication of investigations into structure, such as the officers of our own National Museum are in the habit of contributing to the Proceedings of our Learned Societies and to other private journals. The authorities of the Austrian Museum might, at first sight, appear to be ahead of us in the possession of their recognized official *Annalen*; and there are those among us who would desire the founding of a similar official journal with its attendant restrictions for our own National Museum. We are very doubtful of the advisability of such a step, supposing the trustees were willing to undertake it. As matters stand, the excellent official catalogues which emanate from the building in Cromwell Road fulfil the public demands, and suffice for all purposes of nomenclature which it is a leading function of its authorities to control. The supplementary work, with the publication of which the members of its staff have so long honoured outside bodies, is voluntary. The progress of science in Britain is unique in the extraordinary degree to which it has been furthered by private enterprise; in contributing to the work of our Learned Societies and of those self-supporting institutions to which we have alluded, our Museum officials are encouraging an essentially national system, and fostering a love of science for its own sake. For these if for no other reasons, we would not desire the extension of the Austrian system to our own land.

We cannot close this notice without commenting upon the growing desire to found journals in connection with departments of our native Universities and Colleges. From what we have said, we could hardly be expected to approve of this movement, especially as the interests of such journals are apt to centre in individual aggrandizement, and as the necessity for their continuity may lead to the publication of that which the literature of the sciences might well be spared. We have journals ample for our needs, provided sufficient care be exercised in the selection of their contents. Better far to improve and to extend these, than to tolerate that which in them may be least desirable, adding thereto a "literature" which can only ill compare with that of the last generation of British naturalists.

We note that the Viennese have as yet succeeded in effecting an interchange of publications with but few of our leading Societies, and that their *Annalen* are not yet to be found in a large number of our University and other leading libraries. With respect to this, comparison with foreign countries does not redound to our credit. We can strongly recommend the journal on its merits; and, if the standard of its early volumes be maintained, no working scientific library will be ere long complete without it.

G. B. H.

NOTES.

The programme for the Leeds meeting of the British Association has been issued. The first general meeting will be held on Wednesday, September 3, at 8 p.m., when Prof. W. H. Flower will resign the chair, and Sir Frederick Abel, President-Elect, will assume the Presidency and deliver an address. On Thursday evening, September 4, at 8 p.m., there will be a *soirée*; on Friday evening, September 5, at 8.30 p.m., a discourse on "Mimicry," by Mr. E. B. Poulton, F.R.S.; on Monday evening, September 8, at 8.30 p.m., a discourse on "Quartz Fibres and their Applications," by Prof. C. Vernon Boys, F.R.S.; on Tuesday evening, September 9, at 8 p.m. a *soirée*; and on Wednesday, September 10, the concluding general meeting will be held at 2.30 p.m. The Vice-Presidents are the Duke of Devonshire, the Marquis of Ripon, the Earl Fitzwilliam, the Lord Bishop of Ripon, Sir Lyon Playfair, the Right Hon. W. L. Jackson, M.P., the Mayor of Leeds, Sir James Kitson, and Sir Andrew Fairbairn. The following are the Presidents of the various Sections:—A.—Mathematical and Physical Science, Mr. J. W. L. Glaisher, F.R.S. B.—Chemical Science, Prof. T. E. Thorpe, F.R.S. C.—Geology, Prof. A. H. Green, F.R.S. D.—Biology, Prof. A. Milnes Marshall, F.R.S. E.—Geography, Lieut.-Colonel Sir R. Lambert Playfair. F.—Economic Science and Statistics, Prof. Alfred Marshall. G.—Mechanical Science, Captain A. Noble, F.R.S. H.—Anthropology, Mr. John Evans, V.P.R.S. The local secretaries are Mr. J. Rawlinson Ford, Mr. Sydney Lupton, Prof. L. C. Miall, and Prof. A. Smithells, and the local treasurer, Mr. E. Beckett Faber.

The annual meeting for the election of Fellows of the Royal Society was held at the Society's rooms in Burlington House, on June 5, when the following gentlemen were elected:—Sir Benjamin Baker, Robert Holford Macdowall Bosanquet, Samuel Hawkesley Burbury, Walter Gardiner, John Kerr, LL.D., Arthur Sheridan Lea, D.Sc., Major Percy Alexander MacMahon, R.A., Rev. Alfred Merle Norman, Prof. William Henry Perkin, Prof. Spencer Umfreville Pickering, Isaac Roberts, David Sharp, M.B., J. J. Harris Teall, Richard Thorne Thorne, M.B., Walter Frank Raphael Weldon.

Last Saturday the Royal Observatory was inspected by the Board of Visitors. By invitation of Sir G. G. Stokes, the chairman, about 250 ladies and gentlemen interested in astronomy attended to see the instruments and methods employed in the Observatory.

In the House of Commons, on Tuesday, Mr. A. Acland moved that the sum of £350,000, which the Government propose to use for the extinction of the licenses of public-houses, should be applied in England for the encouragement of agricultural, commercial, and technical instruction, and in Wales for like objects. This ingenious scheme did not commend itself to the Chancellor of the Exchequer. The Government, he said, "admired the enthusiasm of the hon. gentleman, but could not assent to his proposal."

It is announced that the Committee of Council on Education have decided, with the sanction of the Treasury, to allocate a fixed sum every year, in the vote for the Science and Art Department, for grants in aid of technical instruction given under the Technical Instruction Act. The sum allocated for the financial year 1891-92 will be £5000. A grant in aid will not necessarily be equal to, and in no case will it exceed, the amount contributed by the local authority out of the rates. Each grant will be computed, as far as possible, on the basis of the amount of the rate spent on subjects of technical instruction other than those for which the Science and Art Department gives aid under the Science and Art Directory. The application from the local authority, which must be sent in before the end of April in each year, should therefore give a certified statement, with the necessary extracts from the accounts of the preceding year, showing how the rate raised has been expended, and especially how any portion may have been applied to instruction in subjects for which grants are not made under the Science and Art Directory.

In the course of the discussion on Mr. Acland's proposal, Mr. Mundella commented severely on the fact that the sum to be allocated under the Technical Instruction Act for the financial year 1891-92 would be only £5000. There was not a canton in Switzerland, he declared, that would not be ashamed of such a paltry provision for technical education. Mr. Goschen replied that he had himself been struck by the smallness of the sum, "but it was the result of the comparatively small demand made by the local authorities. There was every disposition on the part of the Government to meet to the full the requirements under the Act."

THE Science and Art Department announces that it will make grants for the encouragement of instruction in drawing and of manual training in classes connected with elementary schools and in organized science schools. The instruction must be (*a*) in the use of the ordinary tools used in handicrafts in wood or iron; (*b*) given out of school hours in a properly fitted workshop; and (*c*) connected with the instruction in drawing—that is to say, the work must be from drawings to scale previously made by the students. The instruction may be given by one of the regular teachers of the school if he is sufficiently qualified; if not, he must be assisted by a skilled artisan. The work of the class will be examined by the local inspector of the Department, accompanied, if necessary, by an artisan expert, on the occasion of his visit to examine in drawing. If it appears that the school is properly provided with plant for instruction, and that the teaching is fairly good, a grant of 6*s.*, or, if excellent, of 7*s.*, will be made for every scholar instructed, provided (*a*) that he has passed the fourth standard; (*b*) that he has received manual instruction for at least two hours a week for twenty-two weeks during the school year; (*c*) that a special register of attendance is kept; and (*d*) that each scholar on whom payment is claimed is a scholar of the day school and has attended with reasonable regularity. The grant may be reduced or wholly withheld at the discretion of the Department, if it appears that the plant is insufficient or that the instruction is not good.

AUSTRALIAN educational legislators appear to be reconsidering the policy of the payment by results system, and in some instances, at least, to have come to the conclusion that it must be abolished. The Minister of Education in Victoria is said to have a measure drafted with the object of substituting fixed salaries for school teachers for the system of payment by results.

AT the annual general meeting of corporate members of the Institution of Civil Engineers, on June 3, it was pointed out in the Report that the meeting was held on the sixty-second anniversary of the incorporation of the Institution by Royal charter. At that time the number of members was 156, and the gross annual receipts were £447. At the close of the past financial year the number of members was 5872, and the gross receipts for the twelve months amounted to £22,478. This increase—thirty-seven-fold in numbers and fifty-fold in revenue—sufficiently indicated the position which the Institution had taken in connection with the profession it was designed to promote. At the same time the members were reminded that a large rate of increase was by no means desirable.

AT the beginning of May it was found at Howietoun that the supply of water from Loch Coulter had been interfered with on ten successive nights. On an examination being made each morning, a number of eels were discovered in the sluice, where the water is 10 feet deep. Thirty altogether were obtained, all of them proving to be females. One of these, 32 inches in length, and weighing about 2 pounds, was examined. The ovary, which was about 12 inches long *in situ*, and about 30 inches long when unravelled, was calculated to contain 10,077,000 eggs in various stages of development, some, 0·25 mm. in diameter, being nearly ripe. There is little doubt that these eels formed part of a band migrating to the sea (the smaller specimens escaping and the larger being caught); and judging from the condition of the ovary, it would appear that they were impelled by the instinct of reproduction.

THE Medical Section of the French Association for the Advancement of Science proposes to discuss thoroughly, at the approaching meeting at Limoges, the various questions relating to influenza.

THE visit of the Iron and Steel Institute to the United States in the autumn is likely to be in every way most successful. There will be three different sets of meetings—the meetings of the American Institute of Mining Engineers, which take place in New York on September 29 and 30; the meetings of the Iron and Steel Institute, which take place in the same city on October 1, 2, and 3; and the international meeting promoted jointly by those two Societies, which will take place about the middle of October at Pittsburg. The excursions which have been planned by the American Reception Committee, of which Mr. Andrew Carnegie is chairman, provide for about 3000 miles of free transportation through the United States. The principal excursions will take place to the iron ore and copper regions of Lake Superior, to Philadelphia, Harrisburg, and Chicago, where there are large iron and steel engineering works to be inspected, and to the new iron-making district of Alabama. About 300 members of the Iron and Steel Institute and 100 German ironmasters have intimated their intention of taking part in the meetings; and already many have booked passages in the Hamburg-American Company's steamer *Normannia*, leaving Southampton on September 12. The meetings and excursions will last altogether over a month, and will practically embrace every point of interest in the United States within a distance of 1500 miles of New York. Papers have been promised for the meetings by Sir Lowthian Bell, Sir Nathaniel Barnaby, Sir Henry Roscoe, and others. Among those who have intimated their intention of being present at the meetings are Sir James Kitson (President of the Institute), Lord Edward Cavendish, Sir John Alleyne, Sir James Bain, Mr. Hingley, M.P. (President of the Iron Trade Association), Mr. Theodore Fry, M.P., Sir J. J. Jenkins, Sir Thomas Story, Mr. Windsor Richards, Mr. Snelus, F.R.S., and Mr. Edward P. Martin.

IN the House of Commons, on Monday, Mr. Norris and Sir Henry Roscoe put questions to Mr. Chaplin with regard to the change made by him in "the muzzling order." Mr. Chaplin explained that the collar had been substituted for the muzzle only in those districts in which rabies had, it was believed, ceased to exist. The number of cases of rabies during last year was 340. The muzzling order had never at any time been extended to the whole kingdom, and there were no statistics to show what the effect of the order would be if it were made universal. From the progress made already, he anticipated that rabies might be effectually dealt with without any necessity for so stringent a measure.

IN January of the present year two samples of compressed or tablet tea were presented to the Museum of the Royal Gardens, Kew, by Colonel Alexander Moncrieff. In the new number of the *Kew Bulletin* the letter with which these samples were accompanied is printed; and much interesting information as to the making of compressed tea is brought together. Repeated attempts have been made to introduce compressed tea into this country, but never with complete success. "A few years ago," says the *Kew Bulletin*, "two companies were formed for working it, and at the present time there is a company in London which deals exclusively in this article, a sample of which is in the Kew Museums. It is claimed for this tea that it has many advantages over loose tea, the chief of which is that the leaves being submitted to heavy hydraulic pressure all the cells are broken, and the constituents of the leaf more easily extracted by the boiling water, thus effecting a considerable saving in the quantity required for use. Its great advantages over loose tea, however, would seem to be its more portable character, and in the case of long sea voyages, or for use in expeditions, the reduction of its bulk to one-third. The compression of tea into blocks further, it is said, constitutes a real and important improvement in the treatment of tea. These blocks weigh a quarter of a pound each, and are subdivided into ounces, half ounces, and quarter ounces; this insures exactitude in measuring, and saves the trouble, waste, and uncertainty of measuring by spoonfuls. It

also insures uniformity in the strength of the infusion. By compression it is claimed that the aromatic properties of the leaf are retained for a much longer period, and that it is better preserved from damp and climatic changes."

BESIDES the paper on compressed tea, the *Kew Bulletin* for June contains a valuable catalogue of timber trees of the Straits Settlements. Among the late Dr. Maingay's botanical collections—which were acquired for Kew—was a herbarium of the woody plants of the Eastern Indian peninsula, a large proportion of which were new to science. These were accompanied with a series of careful note-books containing descriptions drawn up from fresh specimens, with the native names. The whole material has been worked up at Kew in the preparation by Sir Joseph Hooker of the "Flora of British India," and has proved, the *Bulletin* says, "of inestimable value." In the list now printed botanical identifications are given to the native names comprised in Dr. Maingay's catalogue. In the same number of the *Kew Bulletin* there is an interesting correspondence, in which attention is drawn to the growing of cotton in West Africa, and especially to an attempt which has lately been made to introduce and cultivate experimentally in that region the best forms of Egyptian cotton.

THE *Manchester Guardian* says that many students of science in Lancashire will learn with satisfaction that the Council of the Manchester Literary and Philosophical Society have at last been able to make arrangements for the cataloguing of the Society's unique library. This includes, amongst much other rare and valuable material, the publications for a long series of years past of several hundred foreign Academies and learned Societies.

THE "Association pour la Protection des Plantes" held an interesting exhibition at Montpellier during the recent centennial celebration. This Society, which is now seven years old, aims at the protection of Alpine plants, especially in Switzerland, where many species have been all but destroyed by the depredations of plant-dealers. Among its members are many well-known English men of science. It is doing good work in establishing Alpine botanical gardens, where rare species are preserved.

A BOTANICAL school-garden has recently been instituted in Breslau by the magistracy, for regular supply of plants to the schools of the place, and for enabling teachers to make observations on the spot with their pupils. The cost of the arrangement is about £300. Private schools share the advantages on payment of an annual subscription.

GERMAN papers announce the death of Dr. Anton Felix Schneider, Professor of Zoology and Director of the Zoological Museum at the University of Breslau.

THE measurement of the Rhone glacier in a comprehensive and systematic way has been carried on since 1874 by the Swiss Alpine Club, and the abundant data obtained will shortly be published in separate form. It appears that the glacier was in recession till 1888, but since last year it has been advancing.

Two violent shocks of earthquake were felt at Sofia on June 7, at half-past 6 a.m. The seismic disturbance was accompanied by subterranean noises. Its direction was from south to north. No damage seems to have been done.

A LARGE water-barometer is now in use in the Saint Jacques Tower, Paris. The glass tube—the longest that has yet been made—is 12 metres 69 centimetres long. The diameter is 2 centimetres. Special openings in the tower were required to allow it to be put in its place. It is connected with a registering apparatus, and it is proposed that a photographic apparatus shall be associated with it, in order that the thermometrical readings of the water in the barometer may also be obtained. The instrument is a very curious one, and may render many services in consequence of its considerable sensitiveness. During thunderstorms it is especially active.

MR. R. H. SCOTT has contributed a note on thunderstorms to *Longman's Magazine* for June, showing various peculiarities in their behaviour in this country and abroad. These storms are generally divided into two groups: (1) heat thunderstorms (the summer type), and (2) cyclonic thunderstorms, which occur principally in autumn and winter. The frequency of the storms is much greater in low latitudes than in high, and their energy is materially moderated by the dampness of the climate, hence our own comparative immunity from them. Certain districts also appear more liable to storms than others; the damage by hail, which frequently accompanies electrical discharges, appears to be greater in Huntingdonshire and neighbouring counties than in other parts of England. From an extensive inquiry by the Berlin Statistical Office, published in 1866, it appears that houses with thatched roofs are struck by lightning much more frequently than slated houses, while houses in towns are less frequently affected than those in the country.

FÖHN winds, it is now known, are due to the descent from a mountain region of locally heated air-currents, when minima are passing. The föhn phenomena of Greenland have been lately studied by Herren Paulsen and Hann (*Met. Zeitsch.*). Over the ice-covered interior in winter (they represent) lies a barometric maximum, and before minima approach from the west, the phenomenon of increase of temperature with height occurs, as in the Alps. The masses of air on the plateau, cooled by radiation, sink as local cold valley winds, by the fjords. But when an approaching depression from the west sets the air in more general motion, the milder air from higher portions of the anticyclone comes down into the fjords as a warm east wind—the föhn. The movement extends as the minimum comes nearer, and the warming effect is not confined to the föhn localities. On one side of the mountain precipitation occurs, causing diminished cooling of the rising air, and thereby a continuance of the föhn on the other side.

THE new number of the Journal of the Bombay Natural History Society (vol. v. No. 1) contains a valuable paper, by Mr. G. W. Vidal, on the venomous snakes of North Kanara. It has been said that no case of the bite of the *Echis* having proved fatal is known. Mr. Vidal thinks that at the present day this statement can hardly need refutation. There is no doubt, he says, that the *Echis* is a far more potent factor in swelling the mortality of the Bombay Presidency than any other venomous species, and it seems to him important that this fact should be more generally known and recognized than it has been hitherto. In all those districts—such as Sind and Ratnagira—where the *Echis* is known to abound, the average mortality from snake-bite is markedly high, whereas the mortality is insignificant in districts where the *Echis* is either rare or absent.

AT the meeting of the Linnean Society of New South Wales on April 30, Mr. R. Etheridge read a paper on the question "Has man a geological history in Australia?" The general want of satisfactory evidence of man's existence in Australia during Post-Tertiary times was commented on, and the various opinions which have been given on the subject were passed in review. A portion of the human tooth found in the Wellington Breccia Cave by the late Mr. Gerard Krefft was described, and the question of its value as evidence, from what is known of its history, was discussed. After considering all the evidence at present forthcoming, the author arrived at the conclusion that the matter could hardly be summed up better than by the very

reasonable and often correctly applied Scotch verdict of "not proven."

IN the annual address, delivered lately by Colonel J. Waterhouse, President of the Asiatic Society of Bengal, and now printed, he speaks highly of the work done by Indian museums and kindred institutions. He says they are exerting "a great educational influence" on "the teeming masses" of India. Native visitors are beginning "to take a really intelligent interest in the collections." Colonel Waterhouse urges that the work of local museums should be confined to the illustration of local products. If objects from other districts are admitted, the name of their place of origin should, he thinks, be distinctly marked upon them, and they should be kept apart from the local collections.

THE U.S. Department of Agriculture has issued an elaborate Report on the English sparrow (*Passer domesticus*) in North America. The Report has been prepared, under the direction of Dr. C. Hart Merriam, ornithologist to the Department, by Mr. Walter B. Barrows, assistant ornithologist. Dr. Merriam claims that it is "the most systematic, comprehensive, and important treatise ever published upon the economic relations of any bird." The new immigrant into the United States is accused of an enormous number of offences; and no one who studies the evidence brought together in this Report will be disposed to say that his evil deeds have been exaggerated. The climatic and other conditions of America have suited the sparrow to perfection, and he has exercised freely all his powers of doing mischief. The evidence set forth relates to the importation, spread, increase, and checks on the increase of the bird; the injury done by him to birds, blossoms, and foliage; the injury to fruits, garden-seeds, and vegetables; the injury to grain; and the relations of the sparrow to other birds, and to insects. All sorts of suggestions for the destruction or abatement of the nuisance are carefully considered. There is also interesting evidence as to the sparrow in Europe and Australia.

A PAPER upon the atomic weight of magnesium and the properties of the pure metal obtained by distillation *in vacuo* is communicated to the current number of the *American Chemical Journal* by Messrs. Burton and Vorce, of Cleveland, U.S. When an attempt is made to distil magnesium in an ordinary hard potash glass tube it is found that the vapour of the metal attacks the glass in a remarkable manner, a black voluminous substance being formed which evolves a spontaneously inflammable gas on treatment with an acid. This black substance is, in fact, magnesium silicide, Mg_2Si, and the explosive gas silicon tetrahydride, SiH_4. When the silicide is brought in contact with dilute acid there remains, after the liberation of silicon hydride and conversion of the magnesium into a salt of the acid employed, a quantity of a yellow substance which possesses the properties of the lower oxide of silicon described by Mabery. Hence it is not possible to use tubes entirely of glass for the distillation of magnesium. But by lining the interior of the heated portion of the tube with an inner tube of thin sheet-iron, magnesium not alloying with iron, the distillation can be conducted with perfect safety. The magnesium was packed in the iron tube in the form of small pieces of ribbon, and the iron tube then placed in an outer glass tube closed at one end and about twice the length of the iron tube. The other end was afterwards drawn out and connected with a Sprengel pump, and the tube exhausted. The apparatus was then laid in a combustion furnace and the tube heated, the closed end near which the iron tube and its magnesium contents had been placed being heated much more strongly than the end nearest the pump. When the iron tube became heated to bright redness the magnesium commenced to volatilize and sublime into the relatively cooler portion, forming at first a black mirror of silicide upon the glass, which protected it from further corrosion. After continuing the heating for about an hour in the case of the distillation of about ten grams of metal, the gas was shut off, and the whole allowed to cool very slowly so as to prevent fracture of the glass, the vacuum being maintained as perfect as possible until quite cold. The distilled magnesium was similarly redistilled three times, the product of the fourth distillation alone, in which no traces of impurities could be detected by analysis, being employed in the atomic weight determinations. The magnesium was generally deposited in the form of a thin crystalline bar of pure white metal which readily separated from the coating of silicide, but in certain of the distillations beautiful isolated crystals of considerable size were formed. Weighed portions of the metal thus purified were converted to the nitrate by means of purified nitric acid diluted with water also specially purified and recently redistilled in a platinum apparatus. The nitrate was then ignited to oxide, first over a sand-bath, and finally to constant weight at the highest temperature of a muffle furnace. From the relation between the weights of metal taken and oxide produced in ten experiments, the mean value of the atomic weight of magnesium if $O = 16$ was found to be 24·287; if $O = 15·95$, $Mg = 24·211$. The highest value found when $O = 16$ was 24·304, and the lowest 24·271. The crystals of magnesium obtained during the distillation were very perfect hexagonal prisms showing no planes but those of the primary prism ∞P, primary pyramid P, and basal plane oP. From measurements of the angles the axial ratio $a : c = 1 : 1·6202$, which agrees tolerably well with the ratio given by Des Cloizeaux from the measurement of crystals obtained by Dumas in 1880. Magnesium is therefore isomorphous with zinc and beryllium, which latter metal it very closely resembles in its angular measurements and the ratio of its axes. In case of Zn, $a : c = 1 : 1·3564$, and for beryllium, $a : c = 1 : 1·5802$.

THE additions to the Zoological Society's Gardens during the past week include two Oak Dormice (*Myoxus dryas*), Central European, presented by Lieut.-Colonel G. M. Cardew; a Vulpine Phalanger (*Phalangista vulpina* ♂) from Australia, presented by Mrs. Waterson; a Silver-backed Fox (*Canis chama* ♂) from South Africa, presented by Captain H. D. Travers, R.M.S. *Tartar*; a Great Kangaroo (*Macropus giganteus* ♀) from Australia, presented by Mr. Henry Irving, F.Z.S.; a Ring-necked Parrakeet (*Palæornis torquatus* ♂) from India, presented by Mr. Arthur O. Cooke; a West African Love Bird (*Agapornis pullaria*) from West Africa, presented by Mrs. Fell; a Chinese Bulbul (*Pycnonotus sinensis*) from China, presented by Lieut.-General Sir H. B. Lumsden, K.C.S.I., F.Z.S.; three Common Peafowl (*Pavo cristatus* ♂ ♀ et juv.) from India, presented by Mrs. Francis Leighton; a Common Kestrel (*Tinnunculus alaudarius*), British, presented by Mr. C. Ashdown, F.Z.S.; a Loggerhead Turtle (*Thalassochelys caouana*) from the Atlantic Ocean, presented by Miss Beatrice Fort; a Grey Monitor (*Varanus griseus*) from the Sahara Desert, presented by Dr. John Murray; a Hawk-headed Parrot (*Deroptyus accipitrinus*) from Brazil, deposited; a Vociferous Sea Eagle (*Haliaëtus vocifer*) from West Africa, a Red-crowned Pigeon (*Erythrænas pulcherrima*) from the Seychelles, purchased; a Japanese Deer (*Cervus sika* ♂), two Bennett's Wallabys (*Halmaturus bennetti* ♂ ♂), a Vulpine Phalanger (*Phalangista vulpina* ♂), a Peacock Pheasant (*Polyplectron chinquis*), a Swinhoe's Pheasant (*Euplocamus swinhoii*), four Spanish Blue Magpies (*Cyanopolius cooki*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

OBJECTS FOR THE SPECTROSCOPE.

Sidereal Time at Greenwich at 10 p.m. on June 12
15h. 24m. 22s.

Name.	Mag.	Colour.	R.A. 1890.	Decl. 1890.
			h. m. s.	° ′
(1) G.C. 4087	—	White.	15 12 57	+56 43
(2) G.C. 4234	—	Bluish.	16 39 51	+24 0
(3) x Serpentis	4	Reddish-yellow.	15 43 48	+18 29
(4) δ Boötis	3	Yellow.	15 11 6	+33 44
(5) α Coronæ	2	Bluish-white.	15 30 0	+27 5
(6) W Cygni	Var.	Reddish.	21 31 53	+44 53

Remarks.

(1) This is a long white nebula in Draco which was described by Sir John Herschel as "a superb ray nebula." The G.C. description is: "Considerably bright; very large; very much extended in the direction 155°; at first very gradually, then pretty suddenly brighter in the middle, where there is a nucleus." In Herschel's 20-foot reflector it was seen to be $7\frac{1}{2}'$ long. The spectrum of the nebula has not been recorded.

(2) This is one of the planetary nebulæ, and according to Dr. Huggins its spectrum shows the three bright lines usually seen in nebulæ. He also noted that F was the faintest line, and that there was a faint continuous spectrum. The spectrum was re-observed by Vogel in 1872, and he observed two additional lines near wave-lengths 518 and 554. It is important that these lines should be confirmed, and comparisons made with the flutings of carbon and manganese at 517 and 558 respectively. The existence of these lines will further tend to prove the connection between comets and nebulæ, for two bands in these positions have frequently been observed in cometary spectra. It is not improbable that a third cometary band, near λ 468, may also appear in the nebula, as a line near that position (λ 470) has been recorded by Dr. Copeland and Mr. Taylor in other nebulæ. Unfortunately, a rather large aperture is required for this observation; with a 10-inch refractor I have not been able to more than glimpse the additional lines seen by Vogel. The G.C. description of the nebula is: "A planetary nebula; very bright; very small; round; disk and border." It is not advisable to employ a cylindrical lens in searching for faint lines, even though the nebula is a small one.

(3) Vogel describes this star as a fine one of Group II., but Dunér states that the bands are narrow, 4 and 5 being little more than lines. He also notes that the spectrum approaches Class II.*a* (Group III.). It is therefore probable that the spectrum is an intermediate one, and will show some of the lines characteristic of Group III. Any differences in these lines, either in positions or relative intensities, from those seen in stars like the sun, should be noted, as they will form valuable criteria for the subdivision of the Class II.*a* stars of Vogel into two groups—one of increasing temperatures (Group III.), and the other decreasing (Group V.).

(4 and 5) The first of these has a spectrum of the solar type, and the second one of Group IV. (Gothard). The usual observations are required in each case.

(6) The range of this variable is very small—5·8–6·2 at maximum to 6·7–7·3 at minimum—and it will be interesting to observe if any changes in spectrum take place at maximum similar to those which occur in stars of greater range with the same type of spectrum. The general spectrum is a "very fine" one of Group II., but so far no variations with change of magnitude have been noted. The period is given by Gore as 120–138 days, and there will be a maximum about June 21.

THE SPECTRUM OF COMET BROOKS (*a* 1890).—I made further observations of this comet on June 6 and 7, and found that it had become considerably brighter since my last observation (NATURE, vol. xlii. p. 112). The tail was also slightly extended. The principal spectroscopic change noted was a diminution in the brightness of the continuous spectrum relatively to the carbon flutings, making the latter more distinct. There was no change in the positions of the bands, and as the comet has now passed perihelion, it is not likely that it will go through any of the higher-temperature stages. As its distance from the sun increases, it should be observed for the cooler stages. The first decided change, according to Mr. Lockyer's investigations, should be the replacing of the present "hot carbon" spectrum for that of "cool carbon," the criterion for which is a fluting near λ 483. This, again, should be replaced by a spectrum consisting mainly of a line in the position of the chief nebula line (λ 500).

In connection with the observations of the comet, I have also made observations of the spectrum of the nebula G.C. 4058 (see notes for June 5). I found that the spectrum of the nebula was irregularly continuous, with a very decided maximum of brightness coincident with the carbon fluting near λ 517. There were also other brightnesses, the positions of which are not yet determined. The whole spectrum is strikingly similar to that of the comet, and as the two objects are not far removed from each other, this is a good opportunity for observers to satisfy themselves that comets and nebulæ are intimately connected.

A. FOWLER.

THE PLANET URANUS.—M. Perrotin, of Nice Observatory, has made some observations of dusky bands on Uranus, similar to those that are seen on Jupiter (*Vierteljahrsschrift des Astronomische Gesellschaft*). The following are some values found for the position-angle:—

1889 31 May	... ...	13°
,,	... ...	35
1 June	... ...	20
7 ,,	... ...	30

The mean value is 24°·5, or about 10° from the plane of the orbit of the satellites, from which it would appear that the plane of the Uranian equator differs little from the trend of the satellites. M. Perrotin also found that the direction of the bands, according to repeated measures, coincided with the longest diameter. The bands do not appear always to have the same aspect, but vary in number and in size in different parts of the surface. This unequal distribution will, it is hoped, afford a means of accurately determining the time of rotation. The oblateness deduced from the measures is said to be not less than $\frac{1}{15}$.

MR. TEBBUTT'S OBSERVATORY.—We have received the Report of this Observatory for the year 1889. A considerable amount of extra-meridian work has been done during the year, observations having been made of some minor planets, phenomena of Jupiter's satellites, and occultations of stars by the moon. Barnard's comet (*a* 1889) and Davidson's comet (*d* 1889) were observed on eight occasions, and Brooks's comet (*e* 1889) on two occasions. The comparison observations that were made have been reduced, and sent to *Astronomische Nachrichten*. Brorsen's periodical comet was carefully searched for, with the help of Dr. Lamp's ephemeris, on December 21 and 25, 1889, and again on January 18, 20, and 22, but without success. Comparisons have been made, both of η Argûs and R Carinæ, with the neighbouring stars, and it is noted that the former star has not sensibly varied in its lustre since the announcement of its sudden increase of magnitude between April 1887 and May 1888. A satisfactory determination of a maximum of the latter star was made in June 1889, and its period determined as 312 days.

NEW ASTEROID.—A minor planet of the 13th magnitude was discovered by M. Charlois at Nice on May 20. This brings the number up to (293).

CORAL REEFS AND OTHER CARBONATE OF LIME FORMATIONS IN MODERN SEAS.[1]

THE vast organic accumulations known as coral reefs are, undoubtedly, among the most striking phenomena of tropical oceanic waters. The picturesque beauty of coral atolls and barrier reefs, with their shallow placid lagoons, and their wonderful submarine zoological and botanical gardens, fixed at once the attention of the early voyagers into the seas of equatorial regions of the ocean. Questions connected with the peculiar form, the structure, the origin, and the distribution of these great natural productions have, from the very outset, puzzled and interested all those who delight in the study of natural things. In this communication we propose to point out and discuss some of the more general phenomena of oceanic deposits, with special reference to the functions of corals and other lime-secreting organisms, and the accumulation of their dead shells and skeletons on the floor of the great oceans.

Coral reefs are developed in greatest perfection in those ocean waters where the temperature is highest and the annual range is least. It may be said that reefs are never met with where the temperature of the surface water, at any time of the year, sinks below 70° F., and where the annual range of temperature is greater than 12° F. Bermuda, which is the coral island the farthest removed from the equator (lat. 32° N.), and one or two other outlying reefs, may be, in a sense, exceptions to this

[1] Paper read on December 2, 1889, before the Royal Society of Edinburgh, by John Murray, LL.D., Ph.D., and Robert Irvine, F.C.S.

statement, for in these exceptional cases the temperature of the ocean water appears occasionally to fall to 66° or 64° F., and there is a wider annual range than 12° F. This condition of high temperature with small range in the temperature of the water is only to be met with in the middle and western portions of the Atlantic and Pacific Oceans and the central parts of the Indian Ocean; consequently, coral reefs flourish along the eastern shores of the continents, where the coasts are bathed by currents of pure oceanic water coming directly from the open sea; while, on the other hand, they are absent along the western shores of the continents, where the water is colder and the annual range is very much greater—for instance, off the western coasts of America and Africa. The *Challenger* observations have also shown that the layers of warm surface waters are much thicker towards the western parts of the great oceans; consequently, reef-forming organisms flourish at a greater depth along the eastern shores of the continents than in positions further to the eastward in the open ocean, where the warm layer of water—over 70° F.—is much thinner. Throughout the temperate and polar regions there are no coral reefs. This is all the more remarkable, seeing that organisms belonging to the same orders, families, and even genera as those which build up coral reefs flourish throughout colder, and even in polar, seas. In these colder seas the representatives of the reef-builders either do not secrete carbonate of lime in their body-walls, or, if they do so, the shells or skeletons are much less massive than in tropical waters. An attentive examination of the animals procured by the dredge and trawl from all depths shows that in descending into deeper water in equatorial regions the amount of carbonate of lime secreted by the animals living on the sea bottom becomes less with increasing depth, and all the calcareous structures of the organisms become less massive with the descent into the deeper and colder water of the abysmal regions. This remark does not, of course, apply to the shells and skeletons of surface organisms which have fallen to the bottom from the surface waters.

Still another illustration of the same fact is furnished by the study of the pelagic organisms collected in the surface and subsurface waters by means of the tow-nets. In the warmest tropical waters there are numerous species of Pteropoda, Heteropoda, Gasteropoda, Foraminifera, and Coccospheres and Rhabdospheres (calcareous Algæ), which lead a purely pelagic existence, and secrete carbonate of lime shells. Mr. Murray estimates from his tow-net experiments that at least 15 tons of carbonate of lime exists in this form at any moment of time in a mass of tropical oceanic water 1 square mile in extent by 100 fathoms in depth.[1] The number of species and individuals of these lime-secreting organisms decreases and the shells become less massive with a wider removal from the equator and an approach to the colder water of the poles, till we find in the surface waters of the polar regions only one or two thin-shelled Pteropods, and one, or at most two, dwarfed species of pelagic Foraminifera. It would appear then that organisms, as a whole or individually, are able to, and actually do, secrete more lime in regions where there is a uniformly high temperature of the ocean water than in those regions where there are great seasonal fluctuations of temperature, or where there is a uniformly low temperature of the water, as in the polar regions and in the deep sea. In temperate seas more carbonate of lime is secreted in the warm summer months than during winter months. Indeed, a high temperature of the sea water is more favourable to abundant secretion of carbonate of lime than high salinity.

An examination of the deep-sea deposits collected by the *Challenger* and other expeditions in all oceans shows that, after the death of the pelagic organisms above referred to, their calcareous shells are rained down on the ocean's bed, and there make up the larger part of the deposits known as Pteropod and Globigerina oozes, as well as a very considerable part of nearly all other marine deposits. If we take the samples of deep-sea deposits collected by the *Challenger* as a guide, then the average percentage of carbonate of lime in the whole of the deposits covering the floor of the ocean is 36·83, and of this carbonate of lime, it is estimated that fully 90 per cent. is derived from the remains of pelagic organisms that have fallen from the surface waters, the remainder of the carbonate of lime having been secreted by organisms that live on or attached to the bottom. If coral muds and sands, together with Pteropod and Globigerina oozes, be considered, then it is estimated that these contain an average percentage of 76·44 of carbonate of lime, and cover about 51,859,400 square miles of the sea bottom. We have little knowledge as to the thickness of these deposits; still such as we have goes to show that in these organic calcareous oozes and muds, we have a vast formation greatly exceeding in bulk and extent the coral reefs of tropical seas; they are most widely distributed in equatorial regions, but some patches of Globigerina ooze are to be found even within the Arctic circle in the course of the Gulf Stream. The following table shows the estimated area of the various kinds of deposits, with the average depth, and average percentage of carbonate of lime in each:—

[1] Murray, "Structure and Origin of Coral Reefs," Proc. Roy. Soc. Edin., 1880, p. 508.

Table showing the Estimated Area, Mean Depth, and Mean Percentage of $CaCO_3$ *of the different Deposits.*

Deposits.		Area, square miles.	Mean depth in fathoms.	Mean per cent. of $CaCO_3$.
Oceanic Oozes and Clay.	Red clay.	50,289,600	2727	6·70
	Radiolarian ooze.	2,790,400	2894	4·01
	Diatom ooze.	10,420,600	1477	22·96
	Globigerina ooze.	47,752,500	1996	64·53
	Pteropod ooze.	887,100	1118	79·26
Terrigenous Deposits.	Coral sands and muds.	3,219,800	710	86·41
	Other terrigenous deposits, blue muds, &c.	27,899,300	1016	19·20

One of the most remarkable facts discovered by the *Challenger* Expedition is that, although the dead shells of these pelagic organisms are rained down on the sea bottom, and in shallower depths accumulate so as to form calcareous deposits of immense extent, still, in other contiguous but deeper areas, these shells do not accumulate on the bottom, being wholly removed either while falling through the water, or shortly after reaching the ocean's floor. The pelagic organisms are as abundant in the surface waters over the one area as over the other, the only apparent difference in the conditions being one of depth. In the shallowest deposits of the open sea, shells, representative of nearly all the lime-secreting surface organisms, are to be found in the deposits. With increasing depth the more delicate ones disappear from the bottom, till, in 1800 or 2000 fathoms, it is rare to find more than traces of Heteropod, Pteropod, or the more delicate pelagic Foraminifera shells in the deposits, while these same delicate shells occasionally make up fully one-half of the carbonate of lime that is present in depths of 700 or 1000 fathoms. Again, in the still greater depths of 3000 and 4000 fathoms and deeper, the Foraminifera, Coccoliths, and Rhabdoliths are either wholly removed, or are represented only by the broken fragments of the thickest and most compact shells, like *Pulvinulina menardii*, *Sphæroidina dehiscens*, or *Globigerina conglobata*. This gradual decrease in the quantity of carbonate of lime in the deposits with increasing depth is well illustrated in the following table, showing the percentage of lime in the samples of deep-sea deposits collected by the *Challenger* towards the central parts of the ocean basins, away from the immediate influence of the *débris* from continental land or volcanic islands.

The organic oozes, including the red clays and the coral deposits, make up a total of 231 samples, and are arranged as follows, showing the percentage of carbonate of lime in relation to depth:—

14 cases	under 500		fathoms,	m. p.c.	86·04.
7 ,,	from 500	to 1000	,,	,,	66·86.
24 ,,	,, 1000	to 1500	,,	,,	70·87.
42 ,,	,, 1500	to 2000	,,	,,	69·55.
68 ,,	,, 2000	to 2500	,,	,,	46·73.
65 ,,	,, 2500	to 3000	,,	,,	17·36.
8 ,,	,, 3000	to 3500	,,	,,	0·88.
2 ,,	,, 3500	to 4000	,,	,,	0·00.
1 ,,	over 4000		,,	,,	trace.

The fourteen samples under 500 fathoms are chiefly coral muds and sands, and the seven samples from 500 to 1000 fathoms contain a considerable quantity of mineral particles from continents or volcanic islands. In all the depths greater than 1000 fathoms

the carbonate of lime is mostly derived from the shells of pelagic organisms that have fallen from the surface waters, and it will be noticed that these wholly disappear from the greater depths. These figures are derived from a study of the *Challenger* deposits alone, but they are confirmed, as to the general result, by an examination of the deposits collected by the U.S.SS. *Tuscarora* and *Blake*, by H.M.SS. *Egeria* and *Investigator*, the ships of the Telegraph Construction and Silvertown Companies, and other ships. One other peculiarity as to the distribution of carbonate of lime organisms on the ocean's floor may be noted. Where these calcareous shells are most abundant on the surface, as in the tropics, the remains of the dead shells are as a rule found at greater depths on the bottom than in temperate or polar regions, where they are relatively much less abundant in the surface waters.

In his paper on the origin of coral reefs, published many years ago, Mr. Murray pointed out that sea-water, rushing in and out of the lagoon twice in the twenty-four hours, would take up and carry away large quantities of the carbonate of lime which, in the form of coral sand and mud, covers the bottom of these shallow basins. Just as the surface shells are dissolved by falling through the layers of ocean water, so in this case the dead coral fragments are dissolved by the sea-water that continually passes over them; in this way, chiefly, he accounted for the formation of lagoons in atolls and barrier reefs.

During the past few years a large number of experiments have been carried on at the Scottish Marine Station for Scientific Research, with the view of throwing some additional light on the oceanic phenomena referred to in the preceding paragraphs, in so far as these relate to the secretion and solution of carbonate of lime under varying conditions. Those dealing with the secretion of carbonate of lime by organisms will be considered in the first place, and afterwards those treating of the solution of the dead carbonate of lime shells and skeletons will be discussed.

A brief account of some of the experiments will show the nature of the investigations, and indicate the results which have been obtained in so far as they bear on the subject with which we are dealing.

Experiment 1. A number of laying hens were shut up in a wooden building, all ordinary sources of lime being withheld. In a few days the eggs, in place of a calcareous shell, had only a membranous covering. Thereafter sulphate, phosphate, nitrate, and silicate of lime were successively added to their otherwise limeless food, and from all these salts they were enabled to form normal shells for their eggs consisting of carbonate of lime.

From the investigations of Irvine and Woodhead it is believed that the lime salts in passing through the blood assume the form of phosphate, which is carried to the point of secretion, where it is decomposed and deposited as carbonate. When magnesium and strontium salts were added to the hens' food the eggs became membranous and shelless.

Ex. 2. Artificial sea-water was prepared, from which carbonate of lime was rigidly excluded. In this water crabs after ecdysis produced the usual exo-skeleton of carbonate of lime from the lime salts, other than carbonate, present in the water.

Ex. 3. The artificial sea-water of Ex. 2, which was perfectly neutral before the introduction of living crabs, in the course of a short time became distinctly alkaline in character. This was found to be due to the decomposition of their effete nitrogenous products, and the formation of carbonate of ammonia, and ultimately of carbonate of lime.

Ex. 4 and 5. Sea-water was mixed with urine and kept at a temperature ranging from 60° to 80° F. After a time the whole of the lime present in the sea-water was thrown down as carbonate and phosphate.

Ex. 6. A number of small crabs were placed in two litres of ordinary sea-water, and were fed with mussel flesh. This water was not renewed, the effete matters from the crabs passing into it. After a few days the crabs died; the water being then in a putrid condition was set aside at a temperature of from 70° to 80° F., when it was found that practically the whole calcium in the sea-water had been thrown down as carbonate of lime.

Ex. 7. We obtained absolutely fresh "liquor" from a number of living oysters, and examined it before decomposition had begun. It appeared to be a mixture of lymph with unchanged sea-water. The specific gravity was 1·023, indicating a considerable admixture of fresh or river water. This liquor contained 0·1889 grammes per litre of total lime in excess of that present in sea-water of the same specific gravity, and its alkalinity was equal to 0·2581 grammes per litre in excess of sea-water of the same specific gravity.

Thus we had in this liquid an accumulation of total lime (in excess of that present in sea-water) amounting to 0·1889 grammes per litre, the greater part of which was in the form of carbonate in solution, presumably in an amorphous or hydrated condition. Apparently this is due to the direct secretion of carbonate of ammonia by the cells of the living animals, which, reacting on the sulphate of lime in the sea-water, is capable of throwing out nine-tenths of the soluble calcium salts present, in the insoluble condition of carbonate. The oyster liquor was found to contain saline ammoniacal salts in enormous excess over that which is present in ordinary sea-water.

Ex. 8. A similar experiment was made with the liquor taken from living mussels. The results coincided with those obtained in Ex. 7.

Theoretically urea plus two molecules of water will give carbonate of ammonia. If, therefore, this substance be a stage in the formation of urea, it is not unnatural to suppose that in shell-forming animals the shell-formation may take place at this stage without the formation of urea at all. In these experiments the usual method for the estimation of saline and albuminoid ammonia could not be followed, and we made use of the following simple adaptation by which we obtained concordant results.

Absolutely pure potash was added to a measured and carefully filtered portion of the sea-water under examination, and the precipitate formed removed by filtration. The clear filtrate was then Nesslerized in the usual manner. We had thus an accurate means of determining between the actual ammoniacal salts and the albuminoid matter, both of which are, as a rule, present in sea-water according to the amount it carries of living and dead organisms. To satisfy ourselves that the addition of pure potash to a fluid containing albuminoids alone does not give rise (immediately) to the production of saline ammonia, we treated pure albumen taken from a newly laid egg in this manner, as also urea, without obtaining any trace of ammoniacal reaction.

These experiments show the alteration in the constitution of the lime salts in sea-water, both by the decomposition of effete matters thrown into the sea by animals, as also by the secretion of carbonate of ammonia by the cell action of the animals.

Sea-water collected among the coral atolls of the Louisiade Archipelago, received from Captain Wharton, F.R.S., Hydrographer to the Admiralty, contained per million parts—

Saline ammonia	0·48
Albuminoid ammonia	0·18
	0·66

whilst water collected by the *Challenger* in the North Atlantic (lat. 30° 20′ N. long. 36° 6′ W.) contained—

Saline ammonia	0·26
Albuminoid ammonia	0·16
	0·42

and water from the German Ocean near land contained—

Saline ammonia	0·13
Albuminoid ammonia	0·13
	0·26

This is exactly what we were led to expect from the experiments enumerated—the greatest amount of saline ammonia being present where the greatest animal life activity existed, as in the waters from the coral sea; and least in the German Ocean winter water where it was at its minimum.

Thus the whole of the lime salts in sea-water may, under these circumstances, be changed into carbonate, and in this way may be presented to the coral and shell builders in the form suitable for their requirements.

The temperature of the water is of great importance in this reaction. In cold water, of which the great bulk of the ocean consists, the decomposition of nitrogenous organic matter is retarded, whereas in tropical surface waters it proceeds with great rapidity. Thus coral-reef builders and pelagic organisms may not only benefit by the decomposition arising from their own effete matter, but also from the undecomposed nitrogenous matter carried to equatorial regions from the cold water of the deep sea, or from polar regions.

The quantity of carbonate of lime normally present in sea-water is exceedingly small; and the opinion hitherto held seems to have been that lime-secreting organisms must pump enormous quantities of sea-water through their bodies in order to be able to separate out a sufficient quantity to form their shells and skeletons.

Bischoff, in his "Chemical and Physical Geology," vol. i. p. 180, estimates that oysters in this way have to deal with an amount of sea-water equal to from 30,000 to 75,000 times the weight of their shells. It seems more probable that the reactions indicated by our experiments render the whole lime salts in sea-water available for coral polyps to build up their structures. In polyps, which unlike the higher animals have no true circulatory system, and where the animal is immersed in sea-water, it is hardly possible to account for the enormous secretion of carbonate of lime in the manner indicated by Bischoff; but if the conclusion we have arrived at be correct, and such animals, in place of secreting urea, secrete carbonate of ammonia, then we have a perfectly reasonable explanation of the phenomenon of coral formation.

As a laboratory experiment, when carbonate of ammonia is added to sea-water, the greater proportion of the calcium in solution is after a time thrown down as carbonate of lime; whilst the magnesium salts remain in solution. So that if the reaction above indicated be that which takes place in sea-water, then to this circumstance may be due the fact that carbonate of magnesia is almost wholly absent from coral reefs and deep sea calcareous formations.

That the amount of nitrogenous organic matter in a state of suspension and solution must be enormous will appear evident when it is remembered that the floor of the ocean, almost throughout its whole extent, is covered with living animals; that the surface of the sea and shallow waters off the coasts are crowded with plants and animals down to a depth of several hundred fathoms. (The *Challenger* experiments have shown that some species of animals flourish in the intermediate depths of ocean water from the surface to the bottom.) The waste products arising from the functional activity of these organisms, and the nitrogenous products arising from the decomposition of their dead bodies, must work continual changes on the internal constitution of sea-water salts, varying according to their amount, the temperature, the sunlight, and other conditions. It has been shown that ammoniacal salts are to be found everywhere in the ocean, but much more abundantly in warm tropical waters than in colder seas—a result no doubt due to the rapid decomposition of the nitrogenous organic matter present at a high temperature, and its retardation in colder water. The ammonia of the air, and all nitrogenous substances carried from the land to the sea, must also effect changes in the internal constitution of sea-water. Indeed, the peculiar pelagic fauna and flora met with in all regions of the ocean, where it is affected by river and coast waters, are as different in relation with the internal constitution of the sea-water salts as with the lower salinity which prevails in these circumstances.

It is well known that organic substances in the presence of alkaline and earthy sulphates become oxidized at the expense of the oxygen of these salts, with the production of carbonic and hydrosulphuric acids, the latter on oxidizing producing sulphuric acid. The greater part of the organic carbon, which it has been pointed out is of enormous amount, must apparently be thus oxidized, producing an equivalent amount of carbonic and sulphuric acids. The effects of this reaction are likely to be more marked in the deeper parts of the ocean, where the motion of the sea-water must be extremely slow, and where consequently the effete products accumulate; in this way the larger amount of lime and carbonic acid and the less amount of oxygen in solution in such waters is to be accounted for. Not only so, but the very existence of such a relatively large quantity of sulphate of lime in sea-water goes far to prove that this reaction must continually take place, seeing that sulphuric acid cannot exist in a free state in the presence of carbonate of lime. Thus it is probable that the quantity of sulphate of lime in solution in the ocean is only limited by the amount of organic decomposition which takes place in its waters. On the other hand, if marine organisms procure the whole of their carbonate of lime from the sulphate of lime by the reaction of ammoniacal salts, then the amount of lime that may be secreted from ocean waters is likewise limited by the amount of organic matter undergoing this oxidation process in the ocean.

Gmelin, in his "Chemistry," vol. ii. p. 191, refers to this decomposition as follows:—

"In hot climates, as on the west coast of Africa, where the water of rivers charged with organic matter mixes with sea-water, hydrosulphuric acid, sometimes to the extent of 6 cubic inches to the gallon, is found in sea-water, even at a distance of 27 miles from the mouth of the rivers."

This is also confirmed from samples of water which we have received, taken from the roadstead of Monte Video by the telegraph ship *Seine*.

If now we turn our attention to the solution of dead carbonate of lime in shells and coral skeletons by the action of sea-water, it will be found that the rate of this solution varies greatly according to the conditions in which these remains are exposed to the solvent power of the water. A large number of experiments have been conducted with the view of determining the solubility of carbonate of lime under its different conditions. It may be pointed out that the normal amount of carbonate of lime dissolved in sea-water is very small, strikingly so (0·1200 grammes per litre) when compared with the vast amount of this substance continually being secreted from the sea by organisms. Sea-water can, however, take up 0·6490 grammes per litre of carbonate of lime in an amorphous (or hydrated) condition, forming a clear supersaturated solution, but after a time not only the excess so added is thrown down, but also sometimes a portion of that normally present in the water itself. It would thus appear that it is unable permanently to retain in solution more of this substance than is usually found present in sea-water. This peculiarity of sea-water, after taking up a large amount of amorphous carbonate of lime, and throwing it out in a crystalline form, accounts for the filling up of the interstices of massive corals with crystalline carbonate in coral islands and other calcareous formations, so that all trace may ultimately be lost of their original organic structure. These experiments show a great diversity as to the amount of carbonate of lime which will pass into solution in sea-water from various calcareous structures in a given time. As a rule, the more definitely crystalline the substance is, the less it is soluble. Calcspar is less soluble than massive varieties of coral, and these again less than the more porous varieties. We have already indicated that amorphous or hydrated carbonate of lime is (in that condition) much more soluble than any other form of the substance. The rate of solution is also much greater when the water is constantly renewed, than when the same water remains in contact with carbonate of lime. The water quickly becomes saturated and unable to exert further solvent action. In this connection we found that different samples of sea-water from different localities possessed very different solvent powers. Especially was this the case between summer and winter waters, the former having distinct solvent action on coral skeletons, whilst with the latter there was hardly any. The lower specific gravity of winter waters may be regarded as to some extent reducing their solvent power, but this is more probably to be attributed to the absence of free carbonic acid—that is, carbonic acid in excess of what is required to saturate the free base in the sea-water as normal carbonate. To test this point, carbonic acid was added to one of these winter waters (which had no solvent action on coral), the quantity added not being sufficient to destroy its alkaline character. It was found that in these circumstances an appreciable amount had been dissolved.

This appears to indicate that there is more carbonic acid in summer than in winter waters in our latitudes, due probably to the increased activity of animal life. Mr. Buchanan's observations on board the *Challenger* show that the carbonic acid present in sea-water, over and above that necessary to form normal carbonate of lime, was subject to great variations. It appears that this is a much more effective agent in the removal of carbonate of lime shells, &c., than the solvent power of sea-water itself (although artificial sea-water quite free from carbonic acid dissolves carbonate of lime). Buchanan's observations have also shown that carbonic acid as a rule is more abundant in bottom than in surface waters; and Reid's experiments show that carbonated sea-waters under high pressure take up more carbonate of lime than that at a normal atmospheric pressure. The fact that carbonic acid is more abundant in deep waters is evidently connected with the respiration, and also the decay, of the animals which live and die on the ocean floor; and also with the decay of those which fall from the surface. The water filling the deeper hollows has also in its passage to the equator passed over thousands of square miles of this floor covered with living animals, and as this water has a very slow motion, and is but slowly renewed, we would expect an accumulation of carbonic acid and deficiency of oxygen in these abysmal depths. When, therefore, carbonate of lime-

secreting animals die at the surface of the water and their bodies fall to the bottom, the shell is exposed to solution from the action of the sea-water through which it passes, and it may be to that of carbonic acid produced by the decomposition of its own organic matter. If the shell be thin, as in the case of Heteropods and Pteropods, it may be wholly removed before reaching the bottom, but the thicker shelled varieties tend to accumulate even in depths of 2000 fathoms, where they are soon covered up by other shells; and being surrounded by sea-water already saturated with carbonate of lime, are preserved from solution, and form vast beds of calcareous ooze. It is found that the amount of carbonate of lime present in such ooze is greater or less according to the depth of water through which the shells pass from the surface to the bottom, and also to the slow renewal of the water in contact with these great lime deposits. In the red clay area the carbonate of lime is almost entirely absent. The deeper waters which cover such areas are more active in the removal of carbonate of lime, not only because of the larger amount of carbonic acid they contain, but doubtless to the deoxidation of alkaline sulphates by organic matter, which, we have already pointed out, gives rise to sulphuric acid, &c. At the same time account must be taken of the great pressure at such abysmal depths, and the fact that the substance of the shells being less compressible than sea-water, they would fall more slowly, and hence would be longer exposed to the action of the deeper layer of water than those near the surface.

What calcareous remains do reach the ocean floor at such abysmal depths represent the hardest and crystalline varieties of carbonate of lime which resist the solvent action of sea-water to the greatest extent.

In this way we appear to have a perfectly rational explanation of the partial disappearance of carbonate of lime shells from the shallower depths, and their total disappearance from all the greater depths of the ocean. It is to be observed that all those shells in which a considerable quantity of organic tissue is associated with the carbonate of lime disappear in solution more rapidly than the shells of the Foraminifera, which contain little organic matter. (During the whole of the *Challenger* cruise only two bones of fishes, other than the otoliths and the teeth, were dredged from the deposits, and all traces of the cetacean bones were removed, except the dense ear-bones and dense Ziphioid beaks.) The remains of crustacean animals were almost wholly absent from deep-sea deposits, with the exception of Ostracode shells and the hard tips of some claws of crabs.

Turning now to the lagoons and lagoon channels of coral islands, it is believed that large quantities of carbonate of lime are in the same way being dissolved from these shallow basins as well as from the deposits of the deep sea, but under somewhat different circumstances. In the case of a shell falling to the bottom of the sea, it is continually brought in contact with new layers of water, which has the same effect as if a continuous stream of water were passing over the shell. In the case of the lagoons this last is what takes place. The water which flows in and out of the lagoons twice in twenty-four hours passes over great beds of growing coral, and from all the observations we have is largely charged with carbonic acid, owing probably to the large number of living animals on the outer reef over which the water passes on its way to the lagoon. This water passes continually over the dead coral and sand of the lagoon, and takes up and removes large quantities of carbonate of lime in solution (as well as suspension), for in these lagoons the spaces covered by dead coral *débris* always greatly exceed the patches of growing coral. Owing to the fact that the water of the lagoon is continually in motion, and constantly renewed, the layer in contact with the bottom of coral sand can never become saturated or unable to take up more lime, as is apparently the case in the layers of water in contact with the Globigerina ooze and other calcareous deep-water deposits.

From the foregoing discussion and observations it is evident that a very large quantity of carbonate of lime is in a continual state of flux in the ocean; now existing in the form of shells and corals, but after the death of the animals passing slowly into solution, to go again through the same cycle.

On the whole, however, the quantity of carbonate of lime that is secreted by animals must exceed what is re-dissolved by the action of sea-water, and at the present time there is a vast accumulation of carbonate of lime going on in the ocean. It has been the same in the past, for with a few insignificant exceptions all the carbonate of lime in the geological series of rocks has been secreted from sea-water, and owes its origin to organisms in the same way as the carbon of the carboniferous formations; the extent of these deposits appears to have increased from the earliest down to the present geological period.

At the present time most of the carbonate of lime carried to the ocean by rivers has been directly derived from calcareous stratified rocks formed by organic agency in the sea in earlier geological ages, but the calcium in these formations was in the first instance derived from the decomposition of the lime-bearing silicates of the earth's original crust, and this decomposition, which is still going on in the sea and on the land surfaces, is a continuous additional source of carbonate of lime.

In considering the analyses showing the average composition of sea salts, one is struck with the relatively small quantity of those very substances which are extracted so largely from sea-water by plants and animals, viz. carbonate of lime and silica. Siliceous deposits are of vast extent, yet silica occurs merely in traces in sea-water; carbonate of lime deposits are of vastly greater magnitude, yet carbonate of lime makes up only $\frac{1}{700}$th part of the saline constituents of sea-water, and only $\frac{1}{8300}$th part of the whole bulk of sea-water. Sulphate of lime is ten times more abundant than the carbonate in sea-water; on the other hand, the river water that is poured into the ocean contains about ten times as much carbonate as it does of sulphate of lime.[1]

The total amount of calcium in a cubic mile of sea-water is estimated from analyses to be 1,941,000 tons, and the total amount of calcium in the whole ocean is calculated at 628,340,000,000,000 tons. The total amount of calcium in a cubic mile of river water is estimated at 141,917 tons, and the total amount of this element carried into the ocean from all the rivers of the globe annually is estimated at 925,866,500 tons. At this rate it would take 680,000 years for the river drainage from the land to carry down an amount of calcium equal to that at present existing in solution in the whole ocean. Again, taking the *Challenger* deposits as a guide, the amount of calcium in these deposits, if they be 22 feet thick, is equal to the total amount of calcium in solution in the whole ocean at the present time. It follows from this that if the salinity of the ocean has remained the same as at present during the whole of this period, then it has taken about 680,000 years for the deposits of the above thickness, or containing calcium in amount equal to that at present in solution in the ocean, to have accumulated on the floor of the ocean. From the data here furnished a number of other interesting speculations might be indulged in, relating to the amount of carbonic acid that has been abstracted from the atmosphere and fixed in carbonate of lime deposits; the total amount of disintegration of lime-bearing siliceous rocks measured in terms of the calcium at present existing in solution in water and fixed in calcareous deposits; the relative proportions of substances secreted from the ocean as compared with other materials derived from the direct disintegration of the land-forming deep-sea deposits; and the apparent accumulation of carbonate of lime formations towards the equatorial regions of the globe. These various matters will, however, be discussed in another place.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The event of the week has been the achievement of Miss Philippa Garrett Fawcett, of Newnham College, who, in Part I. of the Mathematical Tripos, is declared to be "above the Senior Wrangler," Mr. Bennett, of St. John's.

Mr. Sedley Taylor, the delegate from Cambridge to the Sexcentenary Festival of the Montpellier University, in a letter to the Vice-Chancellor on the subject of his mission, writes:—"We had the great satisfaction of seeing Prof. von Helmholtz, Delegate of the University of Berlin, publicly received with much cordiality, and of learning that, on account of his optical researches, which have given such a beneficent impulse to modern ophthalmology, he was subsequently made the object of a special ovation by the Medical Faculty for which the University of Montpellier has long been famous."

Dr. Butler, Master of Trinity College, was on June 2 again elected to the office of Vice-Chancellor for the ensuing academical year.

The John Lucas Walker Research Studentship in Pathology is vacant by the resignation of Dr. William Hunter, of St. John's College, recently elected to a Research Scholarship in

[1] Murray, "Total Rainfall of the Globe," *Scot. Geogr. Mag.*, 1887.

Sanitary Science by the Grocers' Company. The election will take place about August 26. Candidates are requested to apply to Prof. Roy, 2 Wollaston Road, Cambridge, for information. The Studentship is of the annual value of £200, or of such larger sum, not exceeding £300, as the managers shall from time to time determine; and is tenable for three years. The Student is required to devote himself during the tenure of the Studentship to original pathological research. Dr. Hunter's tenure has been marked by his elaborate and valuable researches on pernicious anæmia.

The Professor of Mineralogy (Prof. Lewis) proposes to give a course of elementary lectures on crystallography in the long vacation, beginning on Tuesday, July 8, at 9 a.m. There will also be a practical course on crystallography given by the Demonstrator, beginning on the same day. Fees for lectures £1 1*s.*; for demonstrations £2 2*s.*

The Special Board for Biology and Geology have nominated Miss L. Ackroyd (Newnham College) to occupy the University table at the Laboratory of the Marine Biological Association for one month during the year 1890.

The Mechanical Workshops Enquiry Syndicate were on Thursday, June 5, empowered by a large majority of the Senate to inquire into the conditions and expense of establishing a definite school of engineering in the University.

The number of persons matriculated during the current academical year was on May 29 brought up to 1027, the largest number on record.

At a meeting of the Council of the Cambridge Philosophical Society on Monday, June 2, it was decided, in accordance with the Reports of the adjudicators, Sir W. Thomson, Lord Rayleigh, and Prof. G. H. Darwin, to award the Hopkins Prize for the period 1883-85 to W. M. Hicks, F.R.S., for his memoir upon the "Theory of Vortex Rings" (Phil. Trans., 1885) and for his earlier memoirs upon related subjects; also to award the Hopkins Prize for the period 1886-88 to Horace Lamb, F.R.S., for his paper on "Ellipsoidal Current Sheets" (Phil. Trans., 1887) and for his numerous other papers on mathematical physics.

Prof. J. J. Thomson announces that a course of demonstrations in practical physics, suitable for students who intend taking the Natural Sciences Tripos after passing Part I. of the Mathematical Tripos, will be given during the Long Vacation in the Cavendish Laboratory on Mondays, Wednesdays, and Fridays, at 10 a.m., commencing July 9. Students wishing to attend the course are requested to send in their names to Prof. Thomson before the end of the term.

The Observatory Syndicate publish in the *Reporter* (June 10, 1890) their record of proceedings for May 27, 1889, to May 26, 1890. The astronomical work of observation and reduction has been steadily carrried out, and the report is not marked by any eventful feature.

Dr. D. MacAlister and Prof. Roy have been appointed to represent the University at the Tenth International Medical Congress at Berlin.

The General Board of Studies, with a view to recruiting the finances of the University, especially in the scientific departments, propose to raise the examination and other fees payable by students. As a commencement they propose that the aggregate fees to be paid for the six M.B. examinations be raised from eight guineas to twelve.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 5.—"Account of Recent Pendulum Operations for determining the Relative Force of Gravity at the Kew and Greenwich Observatories." By General Walker, C.B., F.R.S., LL.D.

It is well known that a series of pendulum observations was carried on in India, during the years 1865 to 1873, with two invariable pendulums, the property of the Royal Society. The Observatory of the Royal Society at Kew was chosen as the base station of the operations, and the pendulums were swung there before being sent out to India, and again on their return from India. With a view to connecting the observations with those which had already been taken with other pendulums in other parts of the world, it was intended, on the return of the pendulums from India, to swing them at the Royal Observatory at Greenwich, which was a well-established pendulum station, observed at by General Sir Edward Sabine, the Russian Admiral Lütke, and others. But when the time arrived for making the observations at the Greenwich Observatory, such extensive preparations were being made there for the equipment of expeditions for the observation of the approaching transit of Venus that no room was available for the pendulum operations. It was, therefore, decided to make the connection with Kew by swinging at Kew Kater's convertible pendulum, for determining the absolute length of the seconds' pendulum, which had been swung 40 years previously at Greenwich by General Sabine. This being done, the length of the seconds' pendulum at Kew was found to be 0·0027 of an inch greater than the length which had been previously determined at Greenwich, and consequently that the daily vibration number was three vibrations greater at Kew than at Greenwich. The difference, however, was far too large to be admissible, as the Observatories are nearly in the same latitude, and differ very slightly in height.

In 1881, Colonel Herschel, R.E., was deputed by the Secretary of State for India to take pendulum observations at the two Observatories, and at the old pendulum station in London, and also at some stations in America, with a view to improving and strengthening the connection between the observations in India and those in other parts of the world. On completing his work in America, he handed over the three pendulums which he had employed to officers of the United States Coast and Geodetic Survey, by whom they were taken round the world, and swung at Auckland, Sydney, Singapore, Tokio, San Francisco, and finally at Colonel Herschel's terminal station at Washington.

But when the observations came to be finally reduced, it was found that the difference between Colonel Herschel's results at Kew and Greenwich, as shown independently by the three pendulums, had an extreme range of about seven vibrations in the daily vibration number. The cause of these differences was mysterious and inexplicable, and there was no alternative but to swing the pendulums a second time at the two Observatories.

The revisionary work was undertaken by the Observatory staff at each place, in such intervals of leisure as they could obtain from their regular operations. The final results, by the three pendulums, make the vibration number at Kew in excess of that at Greenwich by 1·56, 1·50, and 0·59, giving an average excess of 1·22.

The correction to this quantity for the excess of height of the Greenwich over the Kew Observatory is − 0·58. Thus, the revisionary operations, reduced to the mean sea-level, make the excess of Kew over Greenwich = 0·64 of a vibration, which may be accepted as very fairly probable.

Royal Microscopical Society, May 21.—Mr. James Glaisher, F.R.S., Vice-President, in the chair.—Mr. Mayall referred to the donation, by the Messrs. Trainini Bros., opticians of Brescia, of an early form of achromatic microscope objective, constructed by the late Bernardini Marzoli, Curator of the Physical Laboratory of the Lyceum of Brescia. The objective was a cemented combination, and was described and figured in the "Commentari della Accademia di Scienze" of Brescia in 1808. This and other works and documents in proof of its authenticity were exhibited.—Mr. Mayall exhibited on behalf of Mr. P. Vallance an eye-piece similar to that shown at the previous meeting by Mr. Goodwin. It was one of two constructed by Mr. Murrell nearly forty years ago, and was provided with a screw which enabled the compound eye lens to be adjusted with reference to the field lens through a space of nearly ½ inch. —Mr. E. M. Nelson read a paper on micrometers, in the course of which he described a new micrometer made for him by Messrs. Powell and Lealand. The subject was illustrated by a drawing upon the board, and the micrometer attached to a microscope and lamp was handed round.—Mr. Thomas Comber's paper on a simple form of heliostat, and its application to photomicrography, was read. Apart from the question of the extreme simplicity of the heliostat, which was mainly due to limiting the reflection of the mirror to the polar direction and deflecting the pencil in the horizontal direction in the axis of the microscope, by means of a fixed mirror placed at half the angle of the latitude above the heliostat mirror, Mr. Comber had rendered important service to photomicrography by showing how the heliostat might be placed close to the microscope so that the error due to slight inaccuracy of the adjustment of the heliostat might escape the optical leverage which took place when the reflected beam was made to travel through a considerable space.

PARIS.

Academy of Sciences, June 2.—M. Hermite in the chair. —On the application of a double plane mirror to the precise

measurement of stellar distances, by MM. Lœwy and Puiseux. In previous communications the authors have developed the theory of the optical system formed by a double plane mirror cut out of a single block of glass in the form of a prism, and placed in front of the object-glass of an equatorial. The properties of the apparatus are now demonstrated, and a practical method of observation deduced.—On the reduction of sulphates of the alkalies by hydrogen and by carbon, by M. Berthelot.—The author discusses in detail the mechanism of the reactions taking place in these reductions, with especial reference to the conditions obtaining during the process of manufacturing sodium carbonate. The equation $K_2SO_4 + 4H_2 = K_2S + 4H_2O$ expresses approximately the final state of the system, but does not at all represent the course of the reaction, which is probably as follows:—

$$(1)\ K_2SO_4 + 4H_2 = KHS + KOH + 3H_2O;$$

the KHS then decomposes.

$$(2)\ 2KHS = K_2S + H_2S,$$

and the H_2S reacts with the KOH.

$$(3)\ KOH + H_2S = KHS + H_2O.$$

Equations (1) and (3) represent exothermic reactions, (2) is the expression of an endothermic dissociation which takes place at the temperature of reduction. In addition to the above an exothermic reaction takes place between the alkaline sulphide and water vapour, thus—

$$(4)\ K_2S + H_2O = KHS + KHO.$$

The reduction by hydrogen takes place at a comparatively low temperature. With respect to the action of carbon upon the alkaline sulphates, it is shown that solid carbon even at a very bright temperature fails to react with the sulphate, but that carbonic oxide at a bright red heat reduces the salt according to the equation—

$$(5)\ K_2SO_4 + 4CO = K_2S + 4CO_2,$$

the reaction being markedly exothermic.—Note by M. Blanchard accompanying the presentation of a work on the "Actions of the Products secreted by Pathogenous Microbes."—On the fossil Hippopotami of Algeria, by M. A. Pomel. The genus Hippopotamus has been represented in Algeria at different times during the Quaternary period, and the author describes the order in which the types succeeded each other. Of four species, two are said to be certainly special, and probably also a third, whilst the last is almost unknown.—Observations of Brooks's comet (a 1890) made with the Brunner equatorial at Toulouse Observatory, by M. E. Cosserat. Observations of the position of the comet, extending from April 28 to May 14, are given.—On the curve representing diffraction phenomena, by M. Ernest Cesaro.—On the characteristic equation of nitrogen, by M. Ch. Antoine. Some experiments by M. Amagat on the compression of nitrogen between 39·5 and 421·1 atmospheres are used to calculate the value of $\frac{pv}{D(\beta + t)}$, where p is the pressure, and v the volume of a gas. Taking $D = 2{\cdot}830 + 0{\cdot}00191p^{1{\cdot}1}$, which, however, can only be taken as a first approximation, the mean value found is 3·10.—On the ballistic electrometer, by M. Gouy.—The month of May 1890 at the Observatory of the Parc de Saint-Maur; the cold of June 1, by M. E. Renou. The month of May was remarkable for low mean pressure, viz. 753 mm. at an altitude of 49·38 m. The mean temperature was 14°·0, or 0°·7 above the average of other years. On June 1 the minimum thermometer 2 metres above the ground registered 2°·7, and the ground thermometer registered 3°·3 below zero at sunset.—On the determination of the molecular weight at the critical point, by M. Philippe A. Guye. M being the molecular weight of any body, k the critical coefficient (the relation of the absolute critical temperature to the critical pressure), and R the specific refractive power, given by the formula of Lorentz and Lorenz, we have $M = 1{\cdot}8\frac{k}{R}$. The author shows the agreement of the results obtained by calculation with those experimentally determined, and claims that his method should rank with the vapour-density and cryoscopic methods of determining molecular weights.—On the chloro-salts of iridium, and the atomic weight of this element, by M. A. Joly. The double chlorides of iridium and potassium and iridium and ammonium are described, and from the results of their analyses the atomic weight of Ir is found to be 192·75 (H = 1); Seubert's value is Ir = 192·744.—On the oxides of manganese obtained in the wet way; second part—manganous acid, by M. A. Gorgeu.—On some new double iodides of bismuth and potassium, by M. Ch. Astre. There are now five of these double iodides known—namely, $(BiI_3)_2$, KI; $(BiI_3)_2$, 2KI, $2H_2O$; $(BiI_3)_2$, 3KI, $2H_2O$; $(BiI_3)_2$, 4KI; and $(BiI_3)_2$, 6KI; of which the three latter are new, and form the subject of the present paper.—On soda-alum, by M. E. Augé. The properties of this body are incorrectly described in text-books. The author contrasts the observed properties with the properties attributed to the compound by most authors.—The *bouquet* of fermented drinks, by M. Georges Jacquemin.—New researches on the origin of omphalocephalic monsters, and on the primitive duality of the heart in the embryos of Vertebrata, by M. Dareste.—On the arrangement of the collections of molluscs at the Natural History Museum, by M. Edmond Perrier.—On the development of blastodermic layers in *Géphyriea tubicola* (*Phoronis Sabatieri*, nov. sp.), by M. Louis Roule.—On the androgynous castration of the *Muscari comosum*, Mill., by the *Ustilago Vaillantii*, Tul., and some remarkable phenomena accompanying the parasitic castration of the *Euphorbia*, by M. Ant. Magnin.—On the æleolithic syenite of Montreal, and on the endomorphous and exomorphous contact modifications of this rock, by M. A. Lacroix.—Action of soluble substances produced by microbes on inflammation, by MM. Charrin and Gamaleia.

CONTENTS.

THURSDAY, JUNE 19, 1890.

BRITISH AND ORIENTAL CICADIDÆ.

Monograph of the British Cicadæ, or Tettigidæ. By G. B. Buckton, F.R.S. Illustrated by more than Four Hundred Coloured Drawings. (London: Macmillan and Co., 1890.)

A Monograph of Oriental Cicadidæ. By W. L. Distant. (Calcutta: Indian Museum. London: H. S. King and Co. 1890.)

THE insects forming the family of the Cicadidæ of Westwood are among the largest of the Homoptera, and by far the largest number of the known species are to be met with in the warm regions of the world. Some fifty years ago but one species of this family seems to have been recorded from Great Britain—it was found in the New Forest, and figured by Curtis as *Cicada anglica.* Curtis thought it did not sing, because a specimen kept in confinement by Mr. Dale for two or three days was mute. Kirby and Spence, however, were informed that it was very noisy, and, adds Prof. Westwood, "analogy would lead to the belief that it does sing, the drums of *C. orni* not being comparatively larger." Weaver found the pupa-case of this insect attached by the legs to the stem of a fern.

Great have been the changes within the last half-century, during which all the above-mentioned well-known names, but that of the respected Professor of Zoology at Oxford, have been numbered among those of the dead; and now the number of the species of the "British Cicadæ"—using this word, however, in a wider sense—is about 230. Mr. G. B. Buckton, F.R.S., so well known for his excellent monograph of the British Aphidæ, has published the first two parts of an illustrated monograph of our native "froghoppers and grassflies."

Although not of large size, like their tropical brethren, our native species are of great interest, and as to this date there has been no serious attempt to publish an adequately illustrated history of even the European forms, the appearance of this monograph is all the more welcome, and its publication will, no doubt, very greatly facilitate the study of these insects.

It is proposed that this monograph shall be published in eight quarterly parts, and these will be illustrated by about eighty coloured plates. Part 1 was issued in January, and Part 2 in April of this year.

The monograph opens with an introduction, in which the author tells us that he proposes to treat his subject under the following heads: Etymology, and the ancient notices of the Cicada or Tetix; classical allusions and poetic myths relating to them; a biographical sketch of the writings and investigations of authors who have considered the subject; a terminology and description of the parts available for classification; general remarks as to their life-history, reproduction, &c.; diagnosis of species, accompanied by coloured representations of the British species of these insects; notes on variation and distribution; remarks as to the probable antiquity of the group, as shown by their remains in the rocks, amber, and fossil resins; and, in addition to all this, in an appendix, there is to be a bibliographical list of the chief modern authors who have studied the Cicadæ; and a short list of ancient and modern quotations, for reference and for use by the curious. Certainly, we have here the programme of a very large and entertaining volume.

We would suggest that Mr. Buckton should not limit his bibliographical list to the "chief authors who have studied the group," but that he should, if even at the cost of cutting out some of the folk-lore, make this list a complete one. Indeed, if we are to judge of the promise by the present performance, it would perhaps be wiser for the author to dwell more on the descriptive and bibliographical portions of his work, than on those appertaining to the literature thereof, for no small research, of a peculiarly special character, would be necessary before one could successfully write the history of the ancient notices of the Cicadæ, recall all the classical allusions that have been made to them, or even give an account of the early scientific writings about them. We agree with the author that "the ordinary scope of a monograph is the description of the forms, life-history, distribution, &c., of the species contained in it," and hence we regret that he should have added so much to his labours by venturing, in this volume, on other fields of research, with which there seems to be some proof that he has not been so familiar. Thus, on p. iii. of the introduction we read that "the first English author who wrote on the Cicada was Dr. Thomas Moufat, or Mouffet, an English physician, who flourished in the reign of James I. In 1634 he wrote, in folio, a curious Latin treatise on zoology, having for its title, 'Insectorum sive minimorum Animalium Theatrum.'" On p. xx. we find a short account of this book, which is said to be "somewhat rare"; it is therefore reasonable to conclude that Moufet's volume was in our author's hands, but, if so, he could never have read over the dedicatory epistle, from which he, however, quotes, with any care. If we are able to judge by his spelling of Moufet's name, even the title-page was not carefully examined. A glance at Hagen's "Bibliotheca Entomologica," or at Burmeister's "Manual of Entomology," would have guarded the author from a great many mistakes.

Moufet was a physician living in London; he was born in 1550, and, according to Burmeister, he died in 1604. From the little known of him, it does not appear that he was an entomologist. His little volume, "Nosomantica," treating of the prognosis of disease, was published in 1588, and he died "in poverty." Conrad Gesner had laboured hard to complete his "Historia Animalium" by a history of insects, based on Wotton, but he died before he had made much progress with it. Pennius took up the subject, worked at it for 15 years, and then too died, leaving many drawings and fragments of descriptions in manuscript; whereupon Moufet tells us he arranged these descriptions in order, "added to them the light of oratory which Pennius wanted, and so constructed" the history referred to. Born during the reign of Mary, Moufet flourished in the days of Elizabeth, and died at or about the time King James ascended the throne. In 1634, when the work of Wotton (of Oxford), Gesner, and Pennius first saw the light, as "wove together" by Moufet, Charles I. was on the English throne; and, as

can be read in the "Epistola," not of Moufet, but of Sir Theodore de Mayerne, in which he dedicates the work to the illustrious Sir William Paddy, Moufet constructed the "History" hoping to acquire fame by dedicating his compilation to the Virgin Queen; but she, as Hume notes, was no great lover of literary or scientific men, and the dedication appears not to have been accepted, and shortly after her death Moufet also died. "Great poverty at home" then delayed the publication, so the book lay for a long time in obscurity, until it was offered to Sir T. de Mayerne by Moufet's apothecary, Darnello. It lay even then in de Mayerne's library for a long time, subject to the attacks of "moths and cockroaches," and that through no fault of his, "but the printers demanded too much money." In the month of May 1634, dedicated to no sovereign, but to the "ever illustrious Paddy," and having been approved of by "Guliel. Bray, of Lambeth Palace," it was published in London by Hope.

Remembering who wrote the "Epistola," it is funny to find Mr. Buckton writing, "Moufat was a true naturalist, and well loved the subject of which he treated. In his Epistola he dilates on the pleasure, &c., felt by the operator, &c." Instead of Moufet one should read Th. de Mayerne, and the operator was William Paddy, and whoever may have been the Frenchman referred to in this same paragraph, assuredly it was not Réaumur, for he was not born until half a century after the publication of Moufet's work. Perhaps enough in the way of criticism has been written about this subject, but it seems right to call attention to the numerous errors of translation from Moufet's Latin text, which errors are the more to be deplored as the translation given in the Rev. Edw. Topsel's "History of Animals," published in 1658, is fairly accurate, and could have been easily referred to. In referring to the text where Moufet writes about the song of the Cicadæ, Mr. Buckton deplores (p. xii.) its want of clearness, and even ventures to emend it, but Moufet's text is not correctly quoted, and in the translation the whole sense of the original is quite lost. Moufet, no doubt, omitted the word λαλιστέραν from his quotation, but the words cited by Athenæus mean, "I have never seen one more loquacious, no, neither a Cercopia, nor a jay, nor a nightingale, nor a Tettiga, nor a turtle-dove."

Moufet may or may not have been disgusted with the luxury of his day, and possibly partook of the Puritanic spirit of the age (p. xxi.), but he could not have intended that the word "magistræ" should have been translated (even with a ?) as "mistresses": the whole of the translation here is indeed curious; the "health-giving diet of one's forefathers," is interpreted to mean the "health-giving tables of the *better* sort"!

Leaving this portion of the subject, we pass on to briefly notice the diagnoses of the species and the coloured plates. We trust that we are not hypercritical if we suggest that the student should have had some clue to the classification adopted in this portion of the work; such may be given in the introduction, but, if so, we presume it will have to explain the sequence of the species and genera in the text, which surely ought to have explained itself. Thus, under the heading, British Cicadæ, comes the genus Cicadetta, and this is followed by "II. Membracidæ, Stål.," with two genera, Centrotus and Gargara, after which we find "Fulgorinæ, Stål.," with III. Tettigometridæ, IV. Issidæ, and V. Cixiidæ; but the next group, the Delphacidæ, is not numbered, so there is no help given one from the name-endings, or the numerals, or, we may add, the typography, as to what Mr. Buckton regards as a family, or a sub-family, nor can we be quite sure always even of the names that he would adopt for the forms described, as, for example, the species given on pp. 28 and 29.

We have thus pointed out a few of the blemishes that to some slight extent mar the early pages of this important and interesting work, and the literary student could easily point out many more in the already published pages of the introductory chapter, still this part is of but secondary value to the entomologist, and a little more attention to the part containing the diagnoses of the genera and species, and the recording the habitats of *all* the British forms, are points that can be easily attended to in the future parts. Of 41 species of the genus Liburnia recorded as British, twenty-seven have no British habitat quoted, unless, indeed, in some few cases, such phrases as "common on marshy lands," "uncommon in England," and "from Mr. Douglas's collection," are to be regarded as such.

The figures are drawn on stone by the author: those of the perfect insects enlarged are very characteristic and pretty, those of the anatomical details would be improved by a little more distinctness in their outlines.

While the British Cicadæ are thus being monographed by Mr. Buckton, those of the Orient are being monographed by Mr. W. L. Distant, the first two parts of a "Monograph of Oriental Cicadidæ" having been published by order of the trustees of the Indian Museum, Calcutta. Part I. is dated July 1889, and Part II. December 1889. They are in large quarto, each containing twenty-four pages and two plates. We have no words but those of praise for this splendid work, which the trustees of the Indian Museum are to be warmly congratulated on publishing. Mr. Distant leaves us in no doubt as to the forms of which he treats: they belong to the sub-order of the Homoptera, and to the family of the Cicadidæ; for this family he adopts two divisions—the sub-families Cicadinæ and the Tibiceninæ—while the diagnoses of the genera and the species leave nothing to be desired. The typography is excellent. A word of commendation is also due to Mr. Horace Knight, to whom the drawing of the figures from nature has been intrusted; one figure on each plate of a species of each genus is represented in colours.

Mr. Distant proposes in this work to fully describe and figure all the species known from continental India and Ceylon, the islands in the Bay of Bengal, in Burma, Tenasserim, the Malay Peninsula, the length and breadth of the Malayan Archipelago, including, but extending eastward of, New Guinea; and, lastly, Eastern Asia, including China and Japan. Thus this monograph will include all the Oriental species. We trust the author may bring this work, so auspiciously commenced, to a successful issue.

MACHINE DESIGN.

The Elements of Machine Design. By Prof. W. Cawthorne Unwin, F.R.S. (London and New York: Longmans, Green, and Co., 1890.)

THIS is the eleventh edition of an excellent and most useful book for engineers and students in the engineering departments in our technical colleges. Prof. Unwin is so well known in the profession that any work of his is sure to receive full attention and careful study; for even in the present day one unfortunately often sees machinery and engineers' tools, the design and construction of which give us cause to wonder how they manage to work at all. The author is one of those Professors whose books are eagerly sought after by practical men for guidance. To say this is to say very much indeed, for engineers have to make their machines "pay" and creditable to themselves; a bad machine tool in a shop is very soon found out by the repairs it requires, and the quality of the work it can produce.

In this, the new edition of the work, the author has found it necessary to divide the book into two parts, the first of which is now before us. It deals principally with the general principles of design, fastenings, and transmissive machinery.

The author, well knowing the conditions of every-day work in the drawing office and shops, has, we are glad to observe, used throughout the standard English units of weight and length. Another good point is that the mathematics used in the calculations are well within the range of the average engineer; at the same time accuracy is obtained in the results, although useless refinements are omitted.

In the chapters on rivetted joints, and the one on journals and the friction of the same in their bearings, the experimental results obtained from experiments inaugurated by the Institution of Mechanical Engineers are fully described and the results tabulated; and they are embodied in the chapters in many useful forms suitable for the guidance of engineers. Under the heading of rivetted joints, it may be interesting to observe that the question of punching *versus* drilling steel or iron plates has solved itself in, at any rate, one first class bridge works in the north, and in this particular works the invariable practice is to drill all the holes throughout the bridge work because it is cheaper, with suitable machinery, to do so. On p. 97 the author does not say whether his remarks apply to boilers as well as other constructions, but to punch an iron boiler-plate is considered bad practice, and a punched steel plate, even if it is annealed afterwards, certainly comes under the same head.

In most of the locomotive works in this country the boilers are drilled, finally, after all the plates are in position, the barrel being fitted to the fire-box casing after each portion has been drilled; and certainly no good locomotive builder would use a punched steel plate in a boiler, even after annealing. One eminent locomotive superintendent, we believe, uses punched steel boiler shell plates; this is probably the only exception in this country, and is generally considered risky and not sound practice. On p. 140 the system of applying the direct stays to the crown of locomotive fire-boxes might have been added and illustrated with advantage.

The illustrations are particularly good, and all represent good practice. The thanks of engineers are due to Prof. Unwin for placing within their reach a volume in which theory and practice are judiciously treated to their great advantage.

OUR BOOK SHELF.

Investigation of the Fur-Seal and other Fisheries of Alaska. Report from the Committee on Merchant Marine and Fisheries of the House of Representatives. (Washington: Government Printing Office, 1889.)

THE fisheries of Alaska are among the great questions of the day, and those of our legislators who wish to take part in the inevitable debate on the subject will do well to possess themselves of the present volume, and digest the large amount of information that it contains. As is well known, the fur-seal fisheries of the Northern Pacific, which supply the ladies' jackets so much prized in Europe, are rented by the Alaska Commercial Company, and produce a considerable revenue to the United States. It is therefore a standing grievance among our American friends, that, as shown by the testimony collected in the present Report, the number of seals on the Prybiloff Islands, whence the principal supply is derived, "has materially diminished during the last two or three years." This is attributed to the fact that a large number of British vessels, "manned by expert Indian seal-hunters," have frequented Bering's Sea, and destroyed "hundreds of thousands of fur-seals." It is shown that, of the seals thus killed on the ocean, not more than one in seven is secured, because a wounded seal sinks so quickly. Thus, for every thousand seal-skins realized by the British sealing-vessels, some seven thousand seals are killed. Now, during the three years 1886–88, it appears that the number of what the Americans call "illicit skins" secured by the British traders was over 97,000, so that, if these calculations are correct, it follows that nearly three-quarters of a million of fur-seals were destroyed by British vessels during that period. American citizens, we are told, "have respected the law, and have made no attempt to take the seals."

While we fully sympathize with the Americans in their view that the fur-seal is a most useful animal, and deserves protection by special legislation, it seems to be doubtful whether they have any right, in their praiseworthy efforts in this direction, to turn a large tract of the Northern Pacific into a "*mare clausum*," without obtaining the consent of other nations. But the arguments by which they justify this somewhat strong proceeding are fully set forth in the present volume, and deserve special study. We may also commend Mr. Dunn's Report as containing a large amount of information on the history and habits of *Callorhinus ursinus*, and some excellently drawn illustrations of what the Americans consider to be the only legitimate method of obtaining this animal's skin.

Pond Life: Algæ and Allied Forms. By T. Spencer Smithson. (London: Swan Sonnenschein and Co., 1890.)

"THE Young Collector" series, to which this hand-book belongs, deals generally with classes of objects which can be permanently preserved. The present volume describes plants which, as the author says, "are not well adapted for preservation." His task, therefore, has been to give an account of the structure and habits of these plants, and to explain how they may be procured in the best form for observation. He begins with information about

the apparatus required, then treats of the Algæ as a class, and the main divisions into which they have been separated by botanists, and in most of the remaining part of the book describes species, "choosing as types of each genus such species as are most likely to be met with, and leaving out those which are either rare or possess few points of interest for the beginner." Mr. Smithson himself points out that the volume leaves much to be sought elsewhere; but, if used intelligently, it will do sound work by preparing the way for wider study.

Rambles and Reveries of a Naturalist. By the Rev. William Spiers, M.A., F.G.S., &c. (London: Charles H. Kelly, 1890.)

Mr. Spiers does not profess to give in this little book a full account of any one of the subjects with which he deals. His aim has been "to awaken or to stimulate a love for Nature in the minds of some who may not as yet have suspected what wondrous and ever-varying beauty lies everywhere about us, in ditch and pond, in rock and stone, in river and sea, on earth and in the skies." With this end in view, he describes, in a series of short sketches, various phenomena which he himself has had opportunities of observing; and he does his work so well that to a good many readers his book may be of considerable service. There is nothing new or brilliant in Mr. Spiers's descriptions; but they are fresh and clear, and display not only a genuine love for Nature, but a capacity for appreciating the scientific significance of many different orders of facts. Besides other essays, the volume includes papers on seaweeds, rambles in Cornwall, a visit to the Channel Tunnel, St. Hilda's snake-stones, tiny rock-builders, and an evening at the microscope.

Sketches of British Sporting Fishes. By John Watson. (London: Chapman and Hall, 1890.)

A prefatory note to the "Sketches" tells us that "the subject-matter has, for the most part, been gleaned directly from the waterside, and should be looked upon more as the notes of a naturalist than the jottings of an angler." Accordingly, it was with anticipation of interest that we turned to the opening chapter, on salmon.

So little is known of the natural history of the salmon, and so great is its value, both for sport and for food, that we eagerly scan the pages of a naturalist and an angler who may tell us what he has seen and knows. Mr. Watson has nothing to tell us. He disposes of the salmon in 12 pages, and the impression produced upon us is that his acquaintance with that noble fish is confined to the fishmonger's slab, and to the dinner-table.

The chapter on trout is little more satisfactory. That on grayling is by another hand.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

Coral Reefs, Fossil and Recent.

Dr. von Lendenfeld has (June 12, p. 148) quoted cases to contest my statement that there are no coral reefs whose slopes are known to descend steeply to greater depths than about 4000 feet. I must take these seriatim.

(1) "Fitzroy's no-bottom sounding of 7200 feet at a distance of 6600 feet from the breakers at Keeling Island."

I hope I shall not be misunderstood when I say that I cannot accept this as conclusive evidence. Experience daily shows us how little confidence can be placed in a single deep sounding, taken before the days of suitable apparatus, and with no description of the means employed, either to fix the position exactly, or to obtain the cast. It may be correct, but on the other hand it may not be.

(2) "Maldives, &c., rise from a bank of 1000 fathoms very abruptly."

I cannot find any deep soundings near these groups at all. One sounding of 1243 fathoms at a distance of 10 miles is the closest.

(3) "Bermudas rise abruptly out of a depth of 12,000 to 13,000 feet."

There is only one sounding of 12,000 feet anywhere near Bermuda, and as that is six miles from the nearest shallow water, the isolated Challenger Bank, it represents a slope of only 19°.

In point of fact, very few slopes of coral formations have yet been accurately measured. Among the most remarkable that I know are:—

Bougainville Reef in Coral Sea, which drops perpendicularly from the water-level to 360 feet; at a mean slope of 76° to 780 feet; and at 53° to 1500 feet.

Dart Reef, in same sea, has a mean slope of 64° to 1200 feet.

Macclesfield Bank, a so-called, "drowned" atoll, in China Sea, has a mean slope of 51° to 4200 feet, and possibly more.

The existing conditions of the steep outer slopes of atolls are sufficiently astonishing. All I wish to maintain is that we should argue upon proven facts, and not assumptions, which tend to exaggerate difficulties, and to lead us astray.

With regard to Dr. von Lendenfeld's explanation of the limitation of depths of lagoons, I must await a better before I am convinced. My point is that it is very remarkable that no matter how vast the lagoon, and how deep the steep outer slopes, no lagoon has more than a certain depth, and that such a limited depth that isolated coral heads can spring out of it; and I cannot make this general fact fit with a general theory of subsidence, even when varied by occasional elevations.

The "drowned" atolls are no deeper than others whose rims are at the surface; *vide* Great Chagos Bank, and Suadiva Atoll in Maldives.

W. J. L. Wharton.

June 14.

ELECTRO-MAGNETIC RADIATION.[1]

In order to discover whether actions are propagated in time or instantaneously, we may employ the principle of interference to measure the wave-length of a periodic disturbance, and determine whether it is finite or no. This is the principle employed by Hertz to prove experimentally Maxwell's theory as to the rate of propagation of electro-magnetic waves. In order to confine the experiments within reasonable limits we require short waves, of a few metres' length at most. As the highest audible note gives waves of five or six miles long, and our eyes are sensitive only to unmanageably short waves, it is necessary to generate and observe waves whose frequency is intermediate between them, of some hundred million vibrations per second or so. For this purpose we may use a pair of conducting surfaces connected by a shorter or longer wire, in which is interposed a spark-gap of some few millimetres' length. When the conductors are charged by a coil or electrical machine to a sufficiently high difference of potential for a spark to be formed between them, they discharge in a series of oscillations, whose period for systems of similar shape is inversely proportional to the linear dimensions of the system so long as the surrounding medium is unaltered. When the surrounding non-conducting medium changes, the period depends on the electric and magnetic specific inductive capacities of this medium. Two such systems were shown: a large one, whose frequency was about 60 millions per second; and a small one, whose frequency was about 500 millions per second. The large one consisted of two flat plates, about 30 cm. square and 60 cm. apart, and arranged in the same way as is described by Prof. Hertz in *Wiedemann's Annalen*, April 1888. The

[1] Friday Evening Lecture delivered at the Royal Institution, on March 21, by Prof. G. F. Fitzgerald, F.R.S.

smaller vibrating system consisted of two short brass cylinders terminating in gilt brass balls of the same size, and arranged in the same way as the smaller system described by Prof. Hertz in *Wiedemann's Annalen*, March 1889. This latter system was placed in the focal line of a cylindrical parabolic mirror of thin zinc plate, such as that described by Prof. Hertz in this paper.

These generators of electro-magnetic oscillations may be called electric oscillators, as the electric charge oscillates from end to end. A circle of wire, or a coil in which an alternating current ran, or, if such a thing were attainable, a magnet alternating in polarity, might be called a magnetic oscillator. A ring magnet with a closed magnetic circuit is essentially an electric oscillator, while a ring of ring magnets would be essentially a magnetic oscillator again. The elementary theory of a magnetic oscillator can be derived from that of an electric oscillator by simply interchanging electric and magnetic force. Electricity and magnetism would be essentially interchangeable if such a thing existed as magnetic conduction. The only magnetic currents we know are magnetic displacement currents and convection currents, such as are used in unipolar and some other dynamos. It is in this difference that we must look for the difference between electricity and magnetism.

In order to observe the existence of these electro-magnetic oscillations we can employ the principle of resonance to generate oscillations in a system whose free period of oscillation is the same. A magnetic receiver may be employed, consisting of a single incomplete circle of wire broken by a very minute spark-gap, across which a spark leaps when the oscillations in the wire become sufficiently intense. In order that a large audience may observe the occurrence of sparks, the terminals of a galvanometer circuit were connected, one with one side of the spark-gap, and the other with a fine point which could be approached very close to the other side of the spark-gap. It was observed that, when a spark occurred in the gap, a spark could also be arranged to occur into the galvanometer circuit, and, with a delicate long-coil galvanometer (that used had 40,000 ohms resistance), a very marked deflection can be produced whenever a spark occurs. This arrangement we have only succeeded in working comparatively close to the generator, because the delicacy required in adjusting the two spark-gaps is so great. It can, however, be employed to show that the sparks produced in this magnetic resonant circuit are due to resonance by removing this receiver from the generator to such a distance that sparks only just occur, and then substituting for the single circuit a double circuit, which, except for resonance, should have a greater action than the single one, but which stops the sparking altogether. An electric receiver was also used, which was identical with the generator, and had a corresponding, only much smaller, spark-gap between the two plates. When the plates are connected with the terminals of the galvanometer, upon the occurrence of each spark the galvanometer is deflected. It is not so easy to obtain sparks when the plates are connected with the galvanometer as when they are insulated, and it is this that has limited the use of this method of observation. By making the first metre or so of the wires to the galvanometer of extremely fine wire, so as to reduce their capacity, we have found that the difficulty of getting sparks is less than with thick wires. We have not observed any effect due to the thickness of the wires after a short distance from the receiver.

In the case of the small oscillator, a receiver exactly like the one described by Prof. Hertz in his second paper already quoted was placed in the focal line of a cylindrical parabolic mirror, and its receiving wires were connected with the wires leading to the galvanometer by some very fine brass wire. With the large-sized generator and receiver, which were placed about 3 metres apart, it was shown that the sparking was stopped by placing a thin zinc sheet so as to reflect the radiations from a point close behind the receiver. By means of a long india-rubber tube hung from the ceiling, it was shown how, when waves are propagated to a point whence they are reflected, the direct and reflected waves interfering produce a system of loops and nodes, with a node at the reflecting point. It was explained that these nodes, though places of zero displacement, were places of maximum rotation, and that the axis of rotation was at right angles to the direction of displacement. It was explained that an analogous state of affairs existed in the electro-magnetic vibrations. If the electric force be taken as analogous to the displacement of the rope, the magnetic may be taken as analogous to its rotation, and the two are at right angles to one another. In the ether the electric node is a magnetic loop, and *vice versâ*. Though the two are separated in loops and nodes, they exist simultaneously in a simple wave propagation, just as in a rope when propagating waves in one direction the crest of maximum displacement is also that of maximum rotation. It was explained that by placing the reflector at a quarter of a wave-length from the receiver this would be at an electric loop, and have its sparking increased. It may thus be shown that there are a series of loops and nodes produced by reflection of these electromagnetic forces, like those produced in any other case of reflected wave-propagation. This was Hertz's fundamental experiment, by which he proved that electro-magnetic actions are propagated in time, and by some approximate calculations he verified Maxwell's theory that the rate of propagation is the same as that of light. It follows that the luminiferous ether is experimentally shown to be the medium to which electric and magnetic actions are due, and that the electro-magnetic waves we have been studying are really only very long light waves.

A rather interesting deduction from Maxwell's theory is that light incident on any body that absorbs or reflects it should press upon it and tend to move it away from the source of light. Illustrating this, an experiment was shown with an alternating current passing through an electro-magnet, in front of which a good conducting plate of silver was suspended. When the alternating current was turned on the silver was repelled. It was explained that as the silver could only be affected by what was going on in its own neighbourhood, and that if sufficiently powerful radiations from a distant source were falling on the silver, it would be acted on by alternating magnetic forces, this experiment was in effect an experiment on the repulsion of light, which was too small to have been yet observed, even in the case of concentrated sunshine. These slow vibrations are not stopped by a sheet of zinc, though much reduced by a magnetic sheet like tin-plate, though the rapid ones are quite stopped by either—thus showing that wave-propagation in a conductor is of the nature of a diffusion.

In all cases of diffusion where we consider the limits of the problem, terms involving the momentum of the parts of the body must be introduced. It appears from elementary theories of diffusion as if it were propagated instantaneously, but no action can be propagated from molecule to molecule, in air, for instance, faster than the molecules move, *i.e.* at a rate comparable with that of sound. In electro-magnetic theory corresponding terms come in by introducing displacement currents in conductors, and it seems impossible but that some such terms should be introduced, as otherwise electro-magnetic action would be propagated instantaneously in conductors. The propagation of light through electrolytes, and the too great transparency of gold leaf, point in the same direction.

The constitution of these waves was then considered, and it was explained that if magnetic forces are analogous to the rotation of the elements of a wave, then an ordinary

solid cannot be analogous to the ether because the latter may have a constant magnetic force existing in it for any length of time, while an elastic solid cannot have continuous rotation of its elements in one direction existing within it. The most satisfactory model, with properties quite analogous to those of the ether, is one consisting of wheels geared with elastic bands. The wheels can rotate continuously in one directionn, and their rotation is the analogue of magnetic force. The elastic bands are stretched by a difference of rotation of the wheels, and introduce stresses quite analogous to electric forces. By making the elastic bands of lines of governor balls, the whole model may have only kinetic energy, and so represent a fundamental theory. Such a model can represent media differing in electric and magnetic inductive capacity. If the elasticity of the bands be less in one region than another, such a region represents a body of higher electric inductive capacity, and waves would be propagated more slowly in it. A region in which the masses of the wheels was large would be one of high magnetic inductive capacity. A region where the bands slipped would be a conducting region. Such a model, unlike most others proposed, illustrates both electric and magnetic forces and their inter-relations, and consequently light propagation.

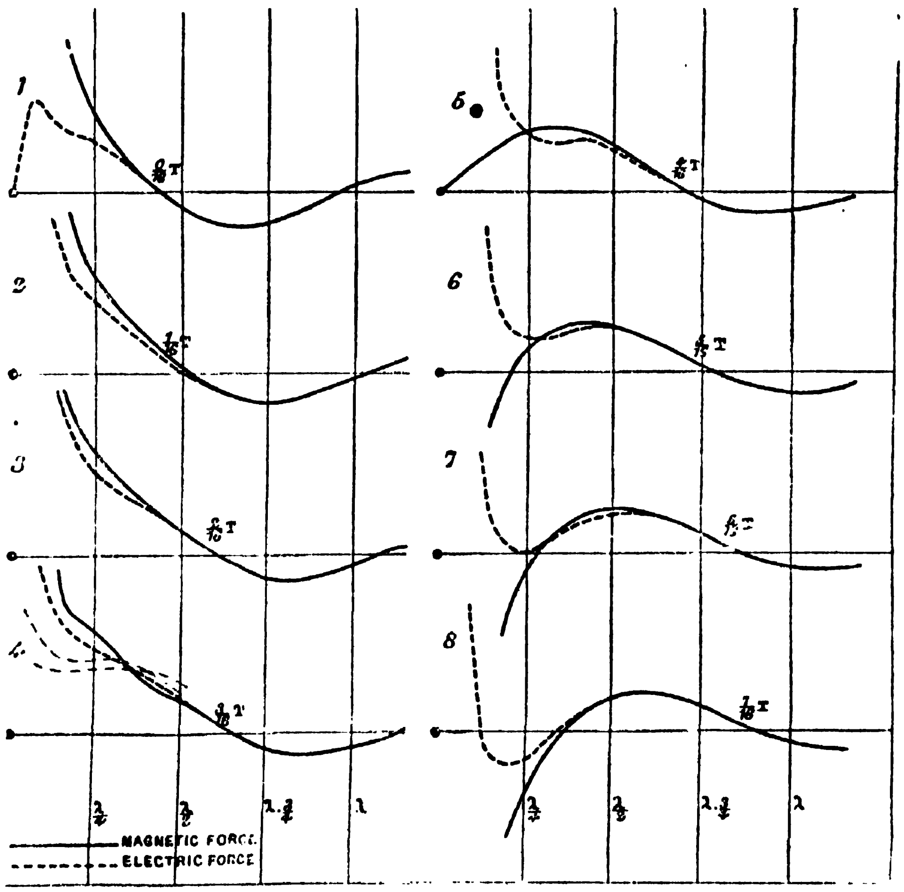
In the neighbourhood of an electric generator the general distribution of the electric and magnetic forces is easily seen. The electric lines of force must lie in planes passing through the axis of the generator, while the lines of magnetic force lie in circles round this axis and perpendicular to the lines of electric force. It is thus evident that the wave is, at least originally, polarized. To show this, the small-sized oscillators with parabolic mirrors were used, and a light square frame, on which wires parallel to one direction were strung, was interposed between the mirrors. It was shown that such a system of wires was opaque to the radiation when the wires were parallel to the electric force, but was quite transparent when the frame was turned so that the wires were parallel to the magnetic force. It behaved just like a tourmaline to polarized light. It is of great interest to verify experimentally Maxwell's theory that the plane of polarization of light is the plane of the magnetic force. This has been done by Mr. Trouton, who has shown that these radiations are not reflected at the polarizing angle by the surface of a non-conductor, when the plane of the magnetic force in the incident vibration is perpendicular to the plane of incidence, but the radiations are reflected at all angles of incidence when the plane of the magnetic force coincides with the plane of incidence. Thus the long-standing dispute as to the direction of vibration of light in a polarized ray has been at last experimentally determined. The electric and magnetic forces are not simultaneous near the oscillator. The electric force is greatest when the electrification is greatest, and the magnetic force when the current is greatest, which occurs when the electrification is zero: thus the two, when near the oscillator, differ in phase by a quarter of a period. In the waves, as existing far from the oscillator, they are always in the same phase. It is interesting to see how one gains on the other. It may be worth observing, again, that though what follows deals with electric oscillators, the theory of magnetic oscillators is just the same, only that the distribution of magnetic and electric forces must be interchanged. Diagrams drawn from Hertz's figures published in *Wiedemann's Annalen* for January 1889, and in NATURE, vol. xxxix. p. 451, and in the *Philosophical Magazine* for March 1890, were thrown on the screen in succession, and it was pointed out how the electric wave, which might be likened to a diverging whirl ring, was generated, not at the oscillator, but at a point about a quarter of a wave-length on each side of the oscillator, while it was explained that the magnetic force wave starts from the oscillator. It thus appears how one gains the quarter-period on the other. The outflow of the waves was exhibited by causing the images to succeed one another rapidly by means of a zoëtrope, in which all the light is used and the succession of images formed by having a separate lens for each picture and rotating the beam of light so as to illuminate the pictures in rapid succession.

As the direction of flow of energy in an electro-magnetic field depends on the directions of electric and magnetic force, being reversed when either of these is reversed, it follows that in the neighbourhood of the oscillator the energy of the field alternates between the electric and magnetic forms, and that it is only the energy beyond about a quarter of the wave-length from the oscilllator which is wholly radiated away during each vibration. It follows that in ordinary electro-magnetic alternating currents at from 100 to 200 alternations per second, it is only the energy which is some 3000 miles away which is lost. If an electro-magnetic wave, having magnetic force comparable to that near an ordinary electro-magnet, were producible, the power of the radiation would be stupendous. If we consider the possible radiating power of an atom by calculating it upon the hypothesis that the atomic charge oscillates across the diameter of the atom, we find that it may be millions of millions of times as great as Prof. Wiedemann has found to be the radiating power of a sodium atom in a Bunsen burner, so that, if there is reason to think that any greater oscillation might disintegrate the atom, it is evident that we are still a long way from doing so. It is to be observed that ordinary light-waves are very much longer than the period of the vibration above referred to. Dr. Lodge has pointed out that quite large oscillators in comparison to molecules—namely, about the size of the rods and cones in the retina—are of the size to resound to light-waves of the length we see, and so might be used to generate such waves. This seems to show that the electro-magnetic structure of an atom must be more complicated than a small sphere or other simple shape with an oscillating charge on it, for the period of vibration of a small system can be made long by making the system complex, *e.g.* a small Leyden jar of large capacity with a long wire wound many times round connecting its coats, could easily be constructed to produce electro-magnetic waves whose length would bear the same proportion to the size of the jar as ordinary light-waves do to an atom. The rate at which the energy of a Hertzian vibrator is transferred to the ether is so great that we would expect an atom to possess the great radiating power it has. This shows, on the other hand, how completely the vibrations of an atom must be forced by the vibrations of the ether in its neighbourhood, so that atoms, being close compared with a wave-length, are, in any given small space, probably in similar phases of vibration. It is interesting to consider this in connection with the action of molecules in collision as to how far the forces between molecules after collision is the same as before. In the same connection the existence of intra-atomic electro-magnetic oscillations is interesting in the theories of anomalous dispersion. An electro-magnetic model of a prism with anomalous dispersion might be constructed out of pitch, through which conductors, each with the same rate of electro-magnetic oscillation, were dispersed. In theories of dispersion a dissipation of energy is assumed, and it may be the radiation of the induced electro-magnetic vibrations. These can evidently never be greater than the incident electro-magnetic vibration, on account of this radiation of their own energy. In some theories a vibration of something much less than the whole molecule is assumed, and the possibility of intra-atomic electro-magnetic oscillations would account for this. Some such assumption seems also required, in order to explain such secondary, if not tertiary, actions as the Hall effect and the rotation of the plane of polariza-

tion of light, which are, apparently at least, secondary actions due to a reaction of the matter set in motion by the radiation on this radiation.

Some further diagrams were exhibited, plotted from Hertz's theory by Mr. Trouton, to whom much of the matter in this paper is due. They are here reproduced, and show eight simultaneous positions of the electric and magnetic waves during a semi-oscillation of an electric oscillator. The dotted line shows the electric force at various points, and the continuous line the magnetic force. In the first diagram the magnetic force is at its maximum near the origin, while the electric force there is zero. In the second the magnetic energy near the origin has partly turned into electric energy, and consequently electric force begins. The succeeding figures show how the magnetic force decreases near the origin, while the electric force grows, and the waves already thrown off spread away. The change of magnetic force between Figs. 4 and 5 is so rapid, that a few dashed lines, showing interpolated positions, are introduced to show how it proceeds. It will be observed how a hollow comes in the line showing electric force, which gradually increases, and, crossing the line of zero force at about a quarter of a wave-length from the origin, is the source of the electric wave, which, starting with this odds, picks up and remains thenceforward coincident with the magnetic wave. From this origin of electric waves they spread out along with the magnetic waves and in towards the origin, to be reproduced again from this point on the next vibration. These electric and magnetic forces here shown as coincident are, of course, in space in directions at right angles to one another, as already explained. The corresponding diagrams for a magnetic oscillator are got by interchanging the electric and magnetic forces.

A further experiment was shown to illustrate how waves of transverse vibration can be propagated along a straight hollow vortex in water. It was stated that what seemed a possible theory of ether and matter was that space was full of such infinite vortices in every direction, and that among them closed vortex rings represented



matter threading its way through the ether. This hypothesis explains the differences in Nature as differences of motion. If it be true, ether, matter, gold, air, wood, brains, are but different motions. Where alone we can know what motion in itself is—that is, in our own brains—we *know* nothing but thought. Can we resist the conclusion that all motion is thought? Not that contradiction in terms, unconscious thought, but living thought; that all Nature is the language of One in whom we live, and move, and have our being.

THE CLIMATES OF PAST AGES.

II.

WE need not enter on a detailed description of the other vegetable types of the Coal-measure formation; we can only note the abundant occurrence of tree-ferns, and the existence of not very numerous conifers, which amid this strange vegetation are the forms most nearly related to those of our present world.

The geographical extent of this typical flora was extraordinarily great; we trace it from the shores of the Atlantic through the northern half of the Old World to China, and it is also greatly developed in the eastern half of the United States. There, and in China, are the greatest developments of beds of coal. Besides these, we find similar deposits with nearly the same vegetation in the far north, in the American polar archipelago, in Spitzbergen, and Nova Zembla. It is these facts that have led to the conclusion, already mentioned, that in the Carboniferous period a uniform climate prevailed from the equator to the pole, together with a dense atmosphere rich in carbon-dioxide, and impenetrable to the solar rays. And yet a simple examination of the facts assures us that all these suppositions are groundless. In so far as regards the character of the flora, we really know nothing of the temperature requisite to the Calamites, Lepidodendra,

Translation of a Lecture delivered by the late Dr. M. Neumayr before the Society for the Dissemination of Natural Science, at Vienna, on January 2, 1889. Continued from p. 151.

Sigillariæ, and other extinct types. Conifers grow now in very severe climates, and only the tree-ferns really indicate warm climatic conditions. At the present day their chief development is in the tropics, and they require, not indeed great heat, but the absence of frost. We do not, however, know that this was equally the case in former ages; in the Carboniferous period, the highest division of the vegetable kingdom, now so dominant, the flowering plants, were either non-existent, or were sparsely represented only by a few early forms, and it is by no means improbable that these types in their gradual extension have exterminated the tree-ferns in the colder regions to which they formerly extended, and that these latter have lost the power which they once possessed of withstanding frost.

Another fact that has been adduced to prove the former prevalence of a warm climate, is the great thickness of the beds of coal, which, it was assumed, could only have been formed by a luxuriant vegetation stimulated by a high temperature. But this also is incorrect; remarkably rich plant-growths are to be met with also in countries with very severe climates, and indeed few countries surpass, in this respect, the inhospitable Terra del Fuego, with its impenetrable beech forests. Moreover, there is no good ground for the assumption that a luxuriant growth of plants is necessary for the formation of thick beds of fossil fuel. At this present time we know of but one mode in which vegetable remains accumulate in thick beds, and thus exhibit to us the first step of the process of coal formation: this is the formation of peat, which, as is well known, is effected by the most inconspicuous and poorest of plants, viz. certain kinds of mosses. It is not in the towering primæval forests of India and Brazil, nor the mangrove swamps of tropical coasts, but in the moors of the sub-arctic zone, that plant-remains are now being stored up in a form that, in the course of geological ages, may become converted into beds of coal.

A closer examination of these conditions apprises us of certain important facts. The reason why great masses of vegetable remains do not accumulate in warm countries is that, in the presence of a high temperature the decaying plants decompose too rapidly, and speedily disappear; it is only in a cold climate that they are preserved; and we may therefore regard the existence of coal-beds as a proof that at the time of their formation a high temperature did *not* prevail.

Out of the mass of baseless assumptions, then, this tolerably well-founded fact remains, that an arborescent vegetation of the Carboniferous period presents itself in 76° of northern latitude, whereas, at the present day the northern limit of tree-growth nowhere exceeds 72°; and if we assume that there has been no displacement of the earth's axis of rotation, we must conclude that in these high latitudes the mean temperature of the year was formerly some degrees warmer than at this present time; in the temperate zone we may infer, with some probability, a cool climate with moderate heat in the summer and cold in the winter, and with but little frost: in fact, an insular climate, such as our knowledge of the distribution of land and sea in that age presupposes.

So far we have regarded only the conditions obtaining in the north temperate zone and the polar regions. These, however, show certain peculiarities of distribution. The greatest coal deposits are all in the temperate zone, and chiefly concentrated in its middle and northern regions. The most northerly of the great deposits of the productive Coal-measures are those of Scotland, the most southerly those on the border of the central plateau of France; such as lie further north or south are of little importance. In North America, it is true, they extend considerably further south, but none reach to the 30th parallel of latitude: while, in the north, they extend into British North America. The coal of China occurs in the northern provinces, in Shansi, Shensi, and Honan.

Thus we find that the greater deposits are restricted to a zone of variable width, the southern limits of which are between 30° and 45°, the northern between 50° and 60° N. lat.; beds of true coal of the same age are not indeed entirely wanting outside these limits, but they are rare; as a rule we meet with only the characteristic plants, and these gradually disappear as we proceed further south. In a few instances they may be traced as far as Northern Africa and the peninsula of Sinai; but between the tropics the typical flora of the coal formation seems to fail entirely; not a single instance of their occurrence can be cited; and their first reappearance seems to be in the southern temperate zone in the coal-fields of Southern Brazil.

For a long time it was very doubtful what explanation should be given of this phenomenon, whether plant-bearing deposits of this age were altogether wanting in the tropical zone, or whether their development was of so different a character that we had failed to identify them, or finally whether it were due to some other cause. We cannot notice at length the gradual development of our knowledge on this head; we can only sketch out the final results which have been yielded in the last few years. We know now, that in Southern Africa, in India, and Australia, there are extensive deposits of the same age as our productive Coal-measures, with abundant plant-remains, but that these differ very greatly from the contemporaneous growths of our own region. No trace is found of the forms characteristic of our Coal-measures, no Sigillariæ, no Lepidodendrons, no Calamites. Ferns and true Equisetaceæ furnish by far the greater part of the flora; and with these are associated a small number of conifers and Cycads. The commonest and most characteristic form of this flora is the fern genus *Glossopteris*, and accordingly the whole assemblage of associated plants has been termed the *Glossopteris* flora. When put in comparison with our European coal flora, so strange does this seem, that no one would venture to think of it as contemporary until it had been established, by evidence admitting of no question, that such is actually the case.

From this, however, the important result follows that the doctrine of a universal coal flora is altogether false. On the contrary, we find that we have to deal with two very different floral regions, which stand strongly contrasted. And what makes this contrast especially remarkable, and for a long time hindered its true interpretation, is that the *Glossopteris* flora of India, Australia, and South Africa is nearly related to the European flora of a much later period, viz. the Trias.

But the most striking fact connected with this flora is that its first appearance, whether in South Africa, India, or Australia, is associated with deposits of fine argillaceous sand, with numerous stony fragments varying in size from small pebbles to gigantic blocks of many hundredweight, irregularly embedded; they consist for the most part of rocks that do not occur anywhere in the neighbourhood, and must therefore have been transported from a distance, and moreover some among them are scored and scratched. These phenomena, which manifest themselves in three far-distant localities, and according to the latest intelligence seem to recur also in Brazil, bear such striking evidence of the agency of ice in the formation of these deposits, that any doubt on this head seems scarcely any longer admissible, however much it may startle us to find great ice-masses and floating icebergs at the time of the coal formation in regions so far from the poles.

From the facts we have recounted, bearing on the climate of the Coal-measure period, it is abundantly manifest that everything runs counter to the assumption of a uniform

and warm terrestrial climate from the equator to the poles. Geographically we have sharply contrasted floras, and we have moreover widely distributed deposits, in the formation of which great masses of ice must have played a part, and thus the old views are utterly overthrown. But when we go further, and seek to learn from the facts before us what the conditions really were, we are quickly admonished that our knowledge is as yet far too small to admit of any definite representation of these conditions. We may say with much probability that the differences of the floral regions must be ascribed to differences of climate, and that, locally, the temperature was so low as to allow of the formation of great masses of ice; but anything beyond this is quite uncertain, and no one of the assumptions that have been made to explain the conditions of that epoch has any claim to validity. Those early ages present us with so much that is strange to us, the unknown is so vast in comparison with what we know, that we dare not as yet attempt any generalization of our knowledge.

We pass over the formations which succeed the Coal-measures, viz. the Permian, the Trias, the Jura, and the Chalk, and after this enormous interval we turn our attention to Tertiary times. Here begin those modern developments that have resulted in our present world; the chief types of animals and plants are the same as those of our own day; and it is only since the beginning of Tertiary times that mammals predominate among the fauna of the land, whereas in the previous formations this leading part had been played by reptiles.

At that time Europe was far more cut up by inland seas than it now is, and formed a dismembered assemblage of islands and peninsulas. In the first division of the Tertiary age, the Eocene, the seas around its coasts were tenanted by animals of a tropical character. In the later subdivisions, this character was gradually lost. In the Oligocene, a marine fauna of a tropical character extends only to a line which about coincides with the northern limit of the Alps. In the Miocene, which next follows, the fauna even of this part of Europe is, at the utmost, sub-tropical; and, by degrees, the forms which give evidence of a warm climate gradually diminish, so that towards the end of the last division, the Pliocene, the conditions were almost the same as to-day.

What we know of the land organisms agrees entirely with these indications afforded us by the marine fauna, at least in their leading characteristics, since we equally find, at the beginning of Tertiary times in Europe, a predominance of sub-tropical and tropical types, which, later on, were replaced by a flora representative of a temperate climate. In detail, indeed, there are many and not unimportant deviations. Thus, for instance, the flora the remains of which are preserved in the calcareous tufa of Sezanne in Champagne, or in the marls of Gelinde, belongs to the Lower Eocene. The forms here represented are such as at the present time are peculiar to the southern part of the temperate or the sub-tropical zone; numerous evergreen oaks, laurels, cinnamon and camphor trees, various Myrtaceæ, Araliaceæ, figs, magnolias, &c.; many forms point decidedly to a tropical climate, but among them we find also, walnut trees, limes, alders, willows, ivy, and vines, which have an opposite character. Palms and cycads, the specially characteristic forms of hot climates, are absent, or at any rate have not been detected. On the whole, botanists are inclined to infer for that epoch in Central Europe such a climate as now obtains in Southern Japan in 33° N. latitude.

We meet first with truly tropical floral characters in somewhat later deposits, viz. in the Middle and Upper Eocene. At that time there flourished on the mainland and islands of Europe great palms and a number of other plants, whose nearest relatives now exist in tropical Africa, India, and Australia. To judge from the land flora, there was then a maximum of warmth in our neighbourhood (Vienna), from which up to the end of Tertiary times a continuous fall took place. In the Oligocene and Lower Miocene the prevailing character is still that of a tropical or sub-tropical region, but the number of forms that now live in temperate regions has considerably increased; such as now live in Australia occur in remarkable quantity. Then in the Upper Miocene of Central Europe we meet with a flora such as at the present day characterizes the warmer parts of the temperate zone, and in which forms allied to the present flora of North America are especially prominent. In the Pliocene, the latest subdivision of the Tertiaries, the change has progressed still further, and at its end we find in our neighbourhood an assemblage of plants nearly recalling that of the present day, with but a slight intermixture of those of warmer regions.

We may grant generally that these facts prove the existence in Tertiary times of a warmer climate than now prevails in Europe, even though there may be great differences of opinion as to the amount of the difference. Heer, to whom we are indebted for the most important investigations of this subject, has endeavoured to determine the mean annual temperature at certain definite geological epochs from the characters of their respective floras. He found that on the northern border of the Alps in Switzerland, at the epoch of the Upper Oligocene, there was a mean temperature of between 20° and 22° C. (68°–72° F.), such as at the present day is that of Cairo, Tunis, Canton, or New Orleans; at the time of the Upper Miocene, one of 18° or 19° C. (64°–66° F.), corresponding to that of Messina, Malaga, Madeira, and Nagasaki; whereas at the present time the mean annual temperature of Zurich is 8°·73 (47°·7 F.), that of Geneva 9°·67 C. (49°·4 F.). But whereas Geneva and Zurich now lie high above sea-level, we have proofs that in Tertiary times the sea-level was much higher in that neighbourhood than now, therefore that this flora grew at a small height above the sea, which would imply alone an increase of about 3° C. (5½° F.) of temperature. It follows, then, that at the time of the Upper Oligocene the temperature was about 9° C. (16° F.), in that of the Upper Miocene about 7° C. (12° F.) higher than at present.

With respect to these figures, we must, however, bear in mind that in such computations no allowance is made for the acclimatization of species and whole genera in the course of long geological periods, and therefore that the assigned variations of temperature are almost certainly too high. Moreover, we must remember that, at that time, Europe was far more than now interpenetrated by inland seas and straits, and therefore that its climate was more insular, the summers being cooler and the winters warmer than now. But whatever weight we give to these considerations, they are alone insufficient to account for the whole of the difference between the Eocene and the present floras. We must perforce admit that other and deeper-lying causes have co-operated in producing the observed differences.

The examination of the Tertiary floras of high northern latitudes leads us very decisively to a similar conclusion. The various English, American, Danish, and especially the Swedish expeditions have discovered in numerous localities the Tertiary plant-remains of the polar regions, the floras of which have been worked out by Heer. Places which are now among the coldest known spots of the earth have yielded the remains of a rich forest vegetation; nay, within the polar circle itself are found plants which at the present time find even our own latitudes too cold for them. The most northern point from which we have plant impressions is Grinnell Land in the North American archipelago, in 81°45′ N. lat. Its present mean annual temperature is about −20° C. (4° F.). The flora consists chiefly of conifers, among which are our common pine, two species of fir, and the American swamp cypress (*Taxodium distichum*); with these are associated elms, limes, birches, poplars, hazel, and some others, the

temperature requisite for which is estimated at about 8° C. (46° F.).

Much richer is the fossil flora of Spitzbergen, between [illegible] d $78\frac{2}{3}^\circ$ N. lat. Here also conifers are dominant; among foliage trees are present several poplars, also willows, alders, beeches, birches, large-leaved oaks, elms, plane trees, walnuts, magnolias, maples, and others; accordingly the climate of Spitzbergen at that time must have been much the same as the present climate of Northern Germany. A still warmer climate is indicated by the fossil flora of Greenland, which may be compared with the present flora of the shores of the Lake of Geneva.

These are by no means the only instances of a similar kind; analogous discoveries have been made at many different points in high northern latitudes; for instance in Siberia on the lower Lena, on the New Siberian Islands, in Kamtschatka, Alaska, Sitka, Banks Land, and some other points. It is not yet certainly determined to what part of the Tertiary period these fossil remains belong. While some regard them as Miocene or Upper Oligocene, others consider them to be Eocene; and good reasons may be assigned for both these opinions. Whatever may be the final decision is for our present purpose a matter of minor importance. The point we have to insist on is that in the polar regions, the mean temperature of which is now below the freezing-point, and in which only some of the lowest plants exist, there was in Tertiary times a rich forest growth. The difference between those times and the present was so great that for Grinnell Land we cannot estimate it as less than 27° C. (49° F.).

Such a change is absolutely inconceivable so long as we continue to regard as unalterable the present position of the places in question with reference to the pole. We cannot imagine any change in the distribution of land and water, in marine currents, or in any other influential factor, which, at a time comparatively so little distant from the present, could have brought about a luxuriant forest growth in Grinnell Land. This has long been recognized, and in many quarters it has been contended that the only explanation possible is a displacement of the earth's axis of rotation. To this the answer has been that the stations that have yielded the Tertiary plant-remains form a circuit around the pole, a chain from which, as an English geologist has expressed it, the pole can no more escape than a rat from a trap in a ring of terriers.

In point of fact there is no need for assuming so considerable a displacement of the pole since the beginning of Tertiary times. There is, however, ample room within the circle of the northern Tertiary plant stations for such a change, and there are valid grounds for such an assumption. For nowhere do the Tertiary plants reach so far north, and yet nevertheless testify so strongly to the existence of a warm climate as in the quadrant in which lie Grinnell Land, Greenland, and Spitzbergen; when we pass over to the opposite quadrant we find precisely the opposite case, for the Tertiary plants of Alaska, in North-Western America have, in north latitude 60°, scarcely more the character of a southern flora than those of Spitzbergen in lat. 78°.

From these considerations, it seems not improbable that, at the time when these Tertiary plants lived, the pole really had not the same position as now, but was displaced from 10° to 20° in the direction of North-Eastern Asia. The circumstances of the Tertiary deposits in other places outside the polar regions agree very well with this view. In Europe, as we have seen, a very warm climate prevailed universally, but when we turn to other countries we meet with a different result. The flora of the Tertiary formations of the United States give no indication of any essential increase of temperature, and the fossil plants of the probably Miocene and Pliocene formations of Japan, according to the admirable investigations of Nathorst, point to a colder climate than that which now prevails. These facts are obviously eminently favourable to the idea of a displacement of the pole. Curiously enough, we find in the yet but little known Tertiary deposits of the southern hemisphere a somewhat striking confirmation of this view, inasmuch as the marine Tertiary Mollusca which occur in several parts of the Chili coast, do not contain a single species indicative of a warmer climate than that of the present day.

Thus, then, it seems very probable that the position of the pole in Tertiary times was different from that of to-day, and only became as at present at the close of that era. But on this assumption the extreme contrasts are only somewhat palliated, the greater divergences somewhat reduced: no complete explanation is afforded of the phenomena. Whatever position we may assign to the pole, those places in which Tertiary forest trees are found were in any case far nearer to it than is the present northern limit of tree-growth; and when we compare the fossil floras of Europe and Japan, we find that the first shows a much greater departure from the present state of things in the direction of a warmer climate than does the latter in the opposite direction. Thus we are led to the conclusion that the climate of Tertiary times in general was somewhat warmer than that of our own day, but by no means to such an extent as that of the lands specially favoured through the displacement of the pole, viz. Grinnell Land, Greenland, Spitzbergen, and Western and Central Europe.

When from the Tertiary age we take another step forward in time, and reach the Pleistocene, the immediate forerunner of our present age, we meet with quite another picture. The remarkable characteristics of this period have been set forth by a skilled hand in this place, and I need only refer to them in a few words and in so far as is specially important in connection with our present subject.

At the setting in of the Pleistocene, the climate seems to have been somewhat warmer than at present: figs, laurels, and vines grew wild in Central Europe, and among animals, we meet with certain fresh-water Mollusca (*Cyrena fluminalis*) which afford a similar indication. Then followed through the greater part of the Pleistocene that extension of enormous ice masses, which, issuing from Scandinavia, Finland, and the Russian Baltic provinces, covered a great part of Europe and advanced to England, Holland, the base of the mountains of Central Germany, the Carpathians, and in Russia as far as Kiew, Woronesch, and Nishni Novgorod. England, Scotland, and Ireland were almost completely glaciated, the ice-sheet covered nearly the whole Alpine region, a broad ice-girdle lay in front of its northern base, and even the small hill-ranges of Central Europe and some of the greater ranges of Southern Europe developed independent glaciers. On a still greater scale, similar phenomena present themselves to us in North America, and in Northern Asia the greater mountains were then glaciated. Also further south, in the Himalaya and the Karakorum were enormous glaciers, and the same in the neighbourhood of the equator in the Sierra di Santa Martha in the northern part of South America. In the southern hemisphere, traces of glaciers occur very extensively in the southern part of the same continent, and according to many accounts also in South Africa.

It was long doubtful whether the glaciation of the northern and southern hemisphere took place simultaneously; but there is now no longer any doubt that such was really the case. Attempts have been made to explain the formation of great ice-accumulations without any depression of temperature, nay even in warm climates, solely as the result of an excessive precipitation of rain and snow, and in consequence of the prevalence of warm winters and cool summers; but these views are wholly

untenable; a depression of temperature is testified to, not only by the extension of the glaciers, but also by the vegetable and animal denizens of the land and the sea. When in Pleistocene deposits of the Mediterranean basin we find Mollusca suddenly appear which now live only in the German Ocean, no other explanation is possible than that the temperature at that time was low.

We need not indeed conclude that an excessive degree of cold was necessary to produce the phenomena of the Glacial period; the height of the snow-line at that time has been computed for many of the mountains of Europe, and from this it has been deduced that the extreme reduction of temperature was at the utmost 6° C. (11° F.), and possibly considerably less. Much has been said and written of the causes which brought about the cold of the Glacial period. Very thoughtful and also very jejune hypotheses have been put forward, all of which have this one characteristic in common, that in some one particular or another they are strongly opposed to the actual facts, and have therefore no validity. With our present knowledge, any explanation is quite impossible. We must content ourselves with recognizing that the cooling was simultaneous, and, as far as research has yet gone, extended over the whole of the globe. It is, then, obviously impossible to attribute it to a displacement of the pole, for in that case a part of the earth must have experienced an increase of temperature; and, in addition to this, we certainly cannot suppose any considerable change in the position of the pole within so comparatively short an interval as separates us from the Glacial epoch. The uniform extension of the phenomenon excludes all those attempted explanations which appeal to geological or geographical changes of the earth's surface, a different distribution of land and sea, changes in the ocean currents, &c., and all points to some agency external to the earth, and therefore acting on it as a whole.

We must specially notice one other circumstance in connection with the Glacial period. It has been observed in many places that the glacial deposits with their scratched pebbles and irregular heaping of their materials do not form a continuous mass, but that, between a lower and upper deposit of glacial character, there is an intermediate bed showing no trace of ice action; at different places, the remains of animals and plants have been met with in this intermediate bed which indicate a somewhat warmer climate, though slightly colder than the present. Thus, in the slaty coal of Utznach and Dürnten in Switzerland, which belongs to this formation, have been found only the remains of plants still growing in the neighbourhood, with the single exception of the mountain pine, which no longer exists in the low plains of Switzerland, but has withdrawn to Alpine heights. These so-called inter-glacial deposits attain in places to a considerable thickness. They show us that during the great Glacial period there intervened a very decided recurrence of a warmer temperature, during which the great ice masses melted away; and from all the indications, this interval, according to human reckoning, must have lasted thousands of years. This page of the earth's history has for us this especial interest, that the oldest certain indications of man's existence in Europe are found in these inter-glacial deposits.

Similar evidence of an interruption of the Glacial period by one of greater warmth is met with in many other parts of the Alpine region, and also on the plains of Northern Germany, in Scandinavia, England, and in different parts of North America, and we must therefore conclude that it was of general occurrence, and that the changes of temperature which brought about the glaciation of an enormous extent of land, and subsequently set it free from its icy covering, were not regularly progressive, but consisted of many changes and oscillations. . . .

Thus we have sketched in a few hasty outlines what we know of the climatic conditions of three periods of the earth's history which are of especial importance for judging such questions. The first of these, of hoar antiquity, was that of the Coal-measures. We have ascertained the existence of distinct floral regions, which in all probability were determined by differences in the distribution of heat; moreover, we have found in deposits far distant from each other evidence of ice action. But in all other points the conditions are so far removed from any of which we have experience, that any further inference is hardly possible. At the utmost we may conclude from the limitation of the greater coal-beds to the temperate zone that the position of the earth's axis and of the pole did not differ very greatly from those of the present day.

When we turn to the much younger formations of the Tertiary age, the conditions are somewhat clearer. In them we recognize, in the first place, the operation of purely local agencies, the distribution of land and water, of ocean currents, &c., but we must also confess that these play but a subordinate part. We have also seen that in certain regions, viz., in Europe, Greenland, Grinnell Land, &c., there prevailed a much warmer climate, which, however, we do not recognize in America; while in Japan, as inferred from the vegetation, the temperature of Tertiary times seems to have been lower than it now is; and we have found in a displacement of the pole and the earth's axis the only probable explanation of these phenomena.

This cause does not, however, suffice to explain all anomalies, and we must assume for all parts of the earth the prevalence of a somewhat warmer climate, an increase perhaps of a few degrees only, which manifests itself particularly in the vegetation of the polar regions.

In the Pleistocene epoch, which is, comparatively speaking, so near to our own, the problem is so far simplified, that one of the two principal factors which determined the deviation from our present climatic conditions—the displacement of the earth's axis—was no longer present; or rather, having regard to the shortness of the time that has since elapsed, was so unimportant that its influence is not traceable. Apart from purely local circumstances, we have, as far as we can judge, only to deal with uniform oscillations of temperature over the whole earth anomalies of the same general character as brought about the general elevation of climatic temperature in the Tertiary age.

If we follow the march of these vicissitudes of temperature, evidently determined by some cosmical agency, we find at the beginning of Tertiary times a moderately warm climate; then a rise during the Eocene, and then a gradual cooling, interrupted possibly by some oscillations, down to a degree nearly corresponding to that now prevailing, at the beginning of the Pleistocene epoch. Then the cooling continued below the present temperature, to a minimum at the time of the greatest glaciation of the land; then a re-warming in the inter-glacial period nearly up to the present temperature; after which cold and glaciation regained the upper hand, finally to give way to the present conditions, which are about midway between the greatest warmth of the Tertiary age and the greatest cold of the Pleistocene.

One fact stands out conspicuously, viz. that these changes progressed very irregularly, and were subject to much oscillation, and the period during which we can approximately follow the course of the change is much too short to enable us to learn the law that regulated it. We cannot decide whether oscillations like those of the Pleistocene will be repeated, and we are now progressing towards another temporary Glacial period, or whether we have to expect the return of a warmer temperature such as prevailed in Tertiary times, or, finally, whether the outcome of all the deviations will be a lasting refrigeration of our climate.

Just as little can we determine at present by what agency all these vicissitudes are brought about; most

plausible and simple would it certainly be were the sun a variable star that at different periods emits different quantities of heat; but for this or any other assumption there is no proof forthcoming. This enigma, like so many others, will some day be solved by man's searching intelligence, but, like all other acquisitions of science, this goal can be won only by assiduous and patient labour. Haply the triumph may not be for our generation; but what we may certainly accomplish is to prepare the way to it, by an accurate and critical collection of the facts.

H. F. B.

NOTES.

IT is expected that about fifty foreign men of science will be present at the Leeds meeting of the British Association. A good many manufacturing firms have promised to open their works during the time at which the meeting is being held; and a Guide to Leeds and the surrounding district, with accounts of the various industries, is being prepared. There will, of course, be excursions to the more interesting places within easy reach of Leeds. The first *soirée* will be given by the Mayor, the second by the Executive Committee. The Yorkshire College will give an afternoon reception.

THE London Mathematical Society has awarded the De Morgan Memorial Medal (given triennially) to Lord Rayleigh, Sec.R.S., for his researches in mathematical physics. The previous awards have been to Profs. Cayley and Sylvester. The medal will be presented at the annual meeting in November next.

THE *conversazione* of the Society of Arts, as we have already announced, will take place at the Natural History Museum, Cromwell Road, on Friday, June 27. The galleries will be lighted with electricity, so that the authorities of the Museum will have a good opportunity of judging how far the electric light is suitable for the building. If the experiment is successful, the system will no doubt soon be permanently established. It may be hoped that in that case the public will not be excluded during an interval between twilight and the lighting of the electric lamps. That plan has been tried at the British Museum, and the results are not encouraging. If the national collections are to have a fair chance of attracting visitors, they must be open continuously from morning until the hour when they are closed for the night.

THE anniversary meeting of the Royal Geographical Society was held on Monday, Sir E. M. Grant Duff, the President, occupying the chair. Mr. Douglas W. Freshfield announced that the Patron's Medal had been awarded to Emin Pasha, and the Founders' Medal to Lieutenant F. E. Younghusband. The Murchison Grant was awarded to Signor Vittorio Sella, for his journey in the Caucasus; the Cuthbert Peek Grant to Mr. E. C. Hore, for observations on the physical geography of Tanganyika; and the Gill Memorial to Mr. C. M. Woodford, for three expeditions to the Solomon Islands. Scholarships and prizes were awarded to students in training colleges. Dr. R. W. Felkin attended, upon instructions by telegram from Zanzibar, to receive the medal for Emin Pasha. The President, in handing the medal to Dr. Felkin, congratulated him upon having done much to make the work of Emin known in England. The Society was not based upon politics, and they simply saw in Emin Pasha one who had from early life given a great deal of attention to botany, natural history, and other subjects. Dr. Felkin, in acknowledgment of the medal, referred to the great services rendered by Emin Pasha to science. Afterwards the Report of the Council was read, and Sir E. M. Grant Duff delivered his presidential address.

AT the meeting of the Scientific Committee of the Royal Horticultural Society on June 10, Mr. Morris called attention to the fact that the Royal Society had assigned £100 "on the recommendation of the Government Grant Committee, for an inquiry into the composition of London fog, with special regard to the constituents of fog injurious to plant life." An informal conversation followed with reference to chemical investigations to be undertaken at the laboratory of University College, under the superintendence of Dr. Oliver.

A DEPUTATION from the Sanitary Institute lately visited Brighton, and met the Mayor and other members of the Committee for the purpose of further considering the Congress and Exhibition to be held in the Pavilion buildings at the end of August. The large dome of the Pavilion, the Corn Exchange, and the Picture Gallery, are all devoted to the Exhibition, but the applications for space are considerably in excess of previous years, and probably some difficulty will be found in accommodating exhibitors. Sir Thomas Crawford is the President. At one of the meetings of the Congress a lecture will be delivered by Mr. W. H. Preece, F.R.S. Dr. B. Ward Richardson, F.R.S., will address a meeting of the working classes.

THE thirty-seventh Report of the Department of Science and Art has been issued.

A LECTURE on the use of alloys in art metal-work, delivered by Prof. Roberts-Austen at the Society of Arts on May 13, is printed in this week's number of the Society's Journal. It is a lecture of great value and interest, and all who read it will cordially agree with the author that "an effort should be made to induce British artificers to employ the materials and methods which their Japanese brethren have used for centuries with such remarkable effect."

IN France much interest is being taken in the question whether a University shall be established in Paris. At a meeting of the General Council of the Paris Faculties, held last Saturday at the Sorbonne, it was agreed that a University with five faculties (Protestant theology, law, medicine, science, and literature), and an upper school of pharmacy, should be formed. "The principal effects of the constitution of the University," says the Paris correspondent of the *Times*, "will be to permit the faculties to make arrangements for the organization of instruction (under the form of schools or institutes) of which the elements are at present scattered in several faculties, and to facilitate a sort of general instruction of a philosophical character, to which the professors of all the faculties will contribute, and which will be addressed to the students. The University will grant, besides professional degrees, diplomas of purely scientific studies to native and foreign students."

M. DEFLERS has just returned to France from his extremely arduous exploration of Southern Arabia at the instance of the Minister of Public Instruction in France. He has brought back large collections of both living and dried plants for the Museum of Natural History.

THE Museum of Natural History in Paris has also received a considerable collection of dried plants gathered in Madagascar by M. Catat.

M. BALANSA is about to return to Tonkin for the purpose of continuing his botanical explorations there; and M. Thollon to the Congo, from which he has already sent interesting collections.

A LABORATORY of Vegetable Biology was opened at Fontainebleau on May 15. It is under the control of M. G. Bonnier, Professor of Botany at the Sorbonne, Paris, to whom applications for leave to pursue researches in the Laboratory should be addressed.

THE Königsberg Physikalisch-Oekonomische Gesellschaft has recently invited a comprehensive discussion of the observations of ground-temperature at Königsberg, published in the Society's *Schriften*, as bearing on our knowledge of heat-movements in the earth and their causes. Attention is called to a previous work by O. Frölich, published at Königsberg in 1868. For the best treatment of the subject a prize of £15 is offered. Papers (in any language), with motto, to be sent in before February 1, 1891.

Science announces that Lieutenant J. P. Finley, of the U.S. Signal Corps, has gone to San Francisco to take charge of the Pacific Coast weather service.

WE learn from *Science* that a work of great importance to navigators is to be undertaken in connection with the report of the U.S. Eclipse Expedition to West Africa, under the direction of Prof. D. P. Todd. This is the preparation of a set of daily weather-maps of both oceans from October to May inclusive, the entire period of the cruise of the U.S. steamship *Pensacola*. The U.S. Hydrographic Office calls attention to the importance of the subject, and the exceptional opportunity presented for utilizing the data already at hand, together with such additional data as may be contributed for this purpose by various Government offices and individual navigators. The scheme determined upon consists in the preparation of a weather map for each day at noon, Greenwich mean time, from October 1, 1889, to May 31, 1890, inclusive, for the entire area between latitude 70° north and 60° south, longitude 20° east and 100° west. In addition to the Greenwich noon observations that are kept regularly for the Hydrographic Office by nearly two thousand voluntary observers, it is earnestly desired that other navigators of these waters, within the limits of time and place mentioned above, may forward to that office such data from their log-books as may be useful in this connection, selecting those observations that come nearest to noon, Greenwich mean time, and stating as many details as possible regarding wind, weather, state of the sea, and velocity and set of currents. Data from land stations are also very important, especially such as are not accessible in any published records. To make this great undertaking a success, however, there must be further and cordial co-operation among the nations interested in the meteorology of this vast area, and among navigators of every nationality. It has long been the desire of the U.S. Hydrographic Office to begin the publication of a pilot chart of the South Atlantic and west coast of South America, and the present undertaking will furnish an admirable basis for this work.

A PAPER on the Mannesmann weldless tubes was lately read before the Society of Arts by Mr. J. G. Gordon, the chair being occupied by Sir Frederick Bramwell, who referred to the importance and interest of the subject, and to the extraordinary means by which the desired result was attained. The process consists in the solution of a purely kinematical problem, viz. the arranging of the velocity ratio of a pair of aconoidal rolls so as to change a solid piece delivered to them at one end into a hollow tube passed out at the other. These rolls revolve at about 200 to 300 revolutions per minute, and by their action on the hot and therefore plastic steel stretch it and make a hollow in the centre. The substance of the metal must be sufficiently homogeneous and plastic, and, in passing through the rolls, it undergoes a violent twisting and stretching action. The bar, in fact, in its passage through the rolls, is twisted as a thread is twisted in a spinning-machine, the material being drawn from the interior. This action was illustrated by one of the exhibits, which consisted of a bar, the ends of which were slightly drawn down under the hammer, so that the rolls could not act on them. A hollow was thus produced in the solid bar of metal, the contents of which were tested by Prof. Finke, of Berlin, and found to contain 99 per cent. of hydrogen of its total volume; the remaining 1 per cent. he considered to be probably nitrogen. In the carrying out of the process, 2000 to 10,000 horse-power is required for from 30 to 45 seconds, according to the dimensions of the tube. Although this is all the time actually required to convert a bar 10 to 12 feet long and 4 inches in diameter into a tube, a certain amount of time is required to adjust the guides, to deliver the bar to the rolls, and to remove the finished tube. The time so spent is employed to accumulate energy in a fly-wheel 20 feet in diameter, weighing 70 tons, and revolving 240 times in a minute, the periphery of which therefore revolves at 2·85 miles per minute; by this means, a steam-engine of 1200 horse-power is quite sufficient to do the work. A peculiar feature of these rolls is that the resulting tube is a test of the material and process. If the metal is homogeneous throughout, and well melted, well rolled, and carefully heated, it makes a perfect tube; but if there is a flaw in the metal, or if it has not been properly heated, the rolls cannot make a tube out of it. The paper, which was illustrated by photographs of the mills and engines, led to a very interesting discussion, in which Sir Frederick Bramwell, Prof. A. B. W. Kennedy, Mr. Alexander Siemens, and others took part.

MESSRS. J. AND A. CHURCHILL have issued the fifth edition of Prof. F. Clowes's "Treatise on Practical Chemistry." The present edition contains several emendations and additions. The author explains that the work is intended to furnish a course of laboratory instruction in practical chemistry, which may precede the higher training of the professional and pharmaceutical chemist and the medical man, and the more special training of the technical chemist and the chemical engineer.

THE sixth volume of "Blackie's Modern Cyclopædia," edited by Dr. Charles Annandale, has been published. The volume begins with "Mona," and ends with "Postulate." The articles, like those of the previous volumes, are remarkably clear, concise, and accurate.

THE third number of the "Indian Museum Notes" consist of a careful paper on silkworms in India, by Mr. E. C. Cotes. The author confines attention to those species which are actually utilized in India for the production of silk.

MR. W. F. KIRBY, author of "A Synonymic Catalogue of Diurnal Lepidoptera," will publish shortly with Messrs. Gurney and Jackson, Mr. Van Voorst's successors, "A Synonymic Catalogue of Neuroptera Odonata or Dragon-flies." He hopes to bring out afterwards the first volume of his "Catalogue of Lepidoptera Heterocera," a work which has engaged his attention for nearly twenty years.

THE editor of the *Naturalists' Gazette* has in the press an "Illustrated Hand-book of British Dragon-flies," which will contain a full description of all the species indigenous to the British Isles, in addition to a quantity of other information.

A NEW gas, methylene fluoride, CH_2F_2, has been obtained by M. Chabrié, and a preliminary account of it will be found in the current number of the *Comptes rendus*. Its chlorine, bromine, and iodine analogues, CH_2Cl_2, CH_2Br_2, and CH_2I_2, have long been known. Methylene iodide is a liquid at ordinary temperatures which solidifies about 4° C. to brilliant leafy crystals. The liquid boils at 182°. Methylene bromide is a liquid boiling at 81°, and the chloride is also a liquid boiling at 41°. The fluoride, completing the graduation of the series, is now shown to be a gas. It is obtained by heating the chloride with silver fluoride. Methylene chloride is generally prepared from methyl iodide, which is placed in a retort, covered with water, and a

stream of chlorine slowly allowed to pass through it. The very volatile methylene chloride distils over, as it is formed, into a condenser which is strongly cooled by a freezing mixture. In order to prepare the new gas, the methylene chloride is placed in a tube of Bohemian glass along with the proper quantity of pure silver fluoride, and the tube sealed before the blow-pipe. It is then heated for half an hour to 180°. In an actual experiment 1·7 gram of methylene chloride and 5·08 grams of anhydrous silver fluoride, specially purified by the method described by Gore, were employed. Upon opening the tube, a great rush of gas occurs, which on collection and analysis is found to consist of methylene fluoride. The density of the gas compared with air was found to be 1·82, which agrees very closely with the theoretical density, 1·81, required for the formula CH_2F_2. Alcoholic potash is found to absorb it completely. Hence, in order to obtain a measure of the amount of carbon contained in the gas, a measured volume was absorbed in alcoholic potash and then treated with acetic acid and potassium permanganate. The alcoholic potash appears to convert it into formaldehyde, $\begin{matrix}H\\H\end{matrix}\!\!>C=O$; this is oxidized by the potassium permanganate to carbonic acid, $\begin{matrix}HO\\HO\end{matrix}\!\!>C=O$, and the acetic acid consequently liberates a volume of carbon dioxide equal to the volume of methylene fluoride experimented upon. This affords a ready mode of demonstrating at the same time the principal properties of the gas and its composition as regards the amount of carbon contained in it. Experiments are now in progress from which it is hoped some knowledge will be gained concerning its physiological action, which it will be interesting to compare with that described by MM. Regnault and Villejean in case of methylene chloride. In a recent communication by M. Moissan upon carbon tetrafluoride, CF_4, an account of which was given in NATURE (May 15, p. 67), it was recommended that metallic tubes should always be employed in these reactions with silver fluoride, inasmuch as fluorides of carbon attack glass with production of carbon dioxide and silicon tetrafluoride; for instance, $CF_4 + SiO_2 = CO_2 + SiF_4$. But M. Chabrié finds that if hard Bohemian glass is used, the product contains only mere traces of the two gaseous impurities mentioned, and, as glass is so much more convenient to manipulate, considers it advisable to use it. The methylene fluoride prepared in the above manner was quite sufficiently pure for all practical purposes.

THE additions to the Zoological Society's Gardens during the past week include a Common Marmoset (*Hapale jacchus*) from South-east Brazil, presented by Mr. Percy Standish; a Malbrouck Monkey (*Cercopithecus cynosurus* ♂) from the Upper Shire, two Grand Galagos (*Galago crassicaudata*) from Mandala, Shire Highland, East Africa, presented by Mr. John W. Moir; two Common Marmosets (*Hapale jacchus*) from South-east Brazil, presented by Mr. W. Norbury; a Common Fox (*Canis vulpes* ♂), British, presented by Mr. Atkins; a Great Crested Grebe (*Podiceps cristatus*), British, presented by Mr. T. E. Gunn; two Green Lizards (*Lacerta viridis*), three Wall Lizards (*Lacerta muralis*), a Dark-Green Snake (*Zamenis atrovirens*), four Common Snakes (*Tropidonotus natrix*), four Marbled Newts (*Molge marmorata*), an Edible Frog (*Rana esculenta*) from the South of France, presented by the Rev. F. W. Haines; eighteen Young Green Turtles (*Chelone viridis*) from Ascension Island, presented by Captain Robinson; a Silvery Gibbon (*Hylobates leuciscus*) from Java, deposited; a Philippine Paradoxure (*Paradoxurus philippensis*) from Zebu Island, Philippines, three Japanese Teal (*Querquedula formosa* ♂ ♀ ♀) from North-east Asia, purchased; an Angora Goat (*Capra hircus*, var., ♂), two Yellow-legged Herring Gulls (*Larus cachinnans*) bred in the Gardens.

Remarks.

(1) The spectrum of this nebula, according to an observation made by Dr. Huggins in 1866, is a continuous one, but this result does not appear to accord with Smyth's description of it as "a fine planetary nebula, . . . large, round, and of a lucid pale blue hue." The G.C. description of it is: "Very bright; large; round; disk with faint, possibly resolvable, border." I know of no later observation of the spectrum than that referred to, but it is important that it should be confirmed, as the colour alone would lead to the supposition that there is something in addition to continuous spectrum. It is indeed possible that we have here a case of a nebula intermediate in condensation between those which give a spectrum of bright lines, and those which give a so-called "continuous" spectrum. In any case the apparent discrepancy between colour and spectrum should be investigated, for it is generally understood that planetary nebulæ with a bluish colour give bright lines.

(2) Dunér describes the spectrum of this star as a magnificent one of Group II. "All the bands 2–10, 6 included, and possibly 1, are visible. They are of extraordinary width and entirely black. The spectrum is totally discontinuous." The usual more detailed observations should be made.

(3) This star has a spectrum generally described as similar to the solar spectrum. The usual more detailed observations, as to whether the star is increasing or decreasing in temperature, are required.

(4) The spectrum of this star is a well-marked one of Group IV., but so far we have no information as to the temperature of the star relatively to others with almost similar spectra.

(5) The spectrum of this variable has not been recorded. The range of variation is from 8·5 to 14 in about 260 days. There will be a maximum about June 20. A. FOWLER.

OBSERVATIONS OF METEORS.—The May number of the *Monthly Notices* of the Royal Astronomical Society contains a catalogue of 918 radiant-points of meteors observed by Mr. Denning at Bristol since 1873, together with a mass of information pertaining to their determination. The total number of meteors seen from 1873 to 1889 was 12,083, and the paths of 9177 of these were registered. The following table shows the horary rate of apparition of the meteors during the various months of the year:—

January ...	6·5	July	11·3
February ...	4·9	August	11·3
March	6·6	September ...	10·3
April	6·6	October	11·8
May	5·2	November ...	11·3
June	4·9	December ...	8·9

The mean horary rate of apparition is therefore 8·3. This is less than would be observed from a place where there is no interference with the light and smoke of a large town, some observations made by Mr. Denning in a different locality increasing the mean horary number to 11·4.

The observations were almost equally distributed between the morning hours, and were usually made between the third and first quarter of the moon, because a bright sky is very effective in obliterating meteor-showers, and therefore moonlight meteors are commonly rare.

As to the relative numbers which appear during the night, the maximum appears to be attained between 2 and 3 a.m., when the rate is nearly double that observed in the early hours of the evening. Two or three meteors have frequently been noticed to appear at nearly the same time and from the same radiant, the probable explanation in such cases being that the

two objects originally formed one mass, which suffered disruption owing to the vicissitudes encountered in planetary space.

The average length of path of all the meteors registered is 10°·9. The average height of either fireballs or shooting-stars has been computed, from thirty-eight instances, to be—

Beginning height ... 71·1 miles.
End height ... ... 48·2 „

From a comparison of a large number of other similar results, the following general average has been deduced :—

Beginning height ... 76·4 miles (683 meteors).
End height ... ... 50·8 „ (736 „).

If fireballs and shooting-stars are separated, the usual heights of disappearance are: fireballs, 30 miles; shooting-stars, 54 miles. A considerable amount of information as to the radiant-points, stationary and otherwise, has been brought together; and, with the catalogue, they render Mr. Denning's paper one of a very important character.

BROOKS'S COMET (*a* 1890).—The following ephemeris has been computed by Dr. Bidschof (*Astr. Nach.*, 2970), and is in continuation of that previously given (vol. xlii. p. 138). The elements have been found from observations at Cambridge, March 21, and Vienna, April 18 and May 24:—

$$T = 1890 \text{ June } 1{\cdot}5360 \text{ Berlin Mean Time.}$$

$$\left.\begin{aligned} \omega &= 68^{\circ}\ 54'\ 39''{\cdot}9 \\ \Omega &= 320\ 20\ 32{\cdot}2 \\ \iota &= 120\ 33\ \ 5{\cdot}4 \end{aligned}\right\} \text{Mean Eq. } 1890{\cdot}0.$$
$$\log q = 0{\cdot}280524$$

Ephemeris for Berlin Midnight.

PHOTOGRAPH OF BROOKS'S COMET (*a* 1890).—A photograph of this comet was obtained at Algiers on May 22 by M. Ch. Trépied (*Comptes rendus*, June 9, No. 23). Two hours' exposure was found necessary.

ASTRONOMICAL TELESCOPES.[1]

BEFORE speaking of the enormous instruments of the present day, with their various forms and complicated machinery, it will be well to give some little time to a consideration of the principles involved in the construction of the telescope, the manner in which it assists the eye to perceive distant objects, and in a brief and general way to the construction and action of the eye as far it affects the use of the telescope, all as a help to consider in which way we may hope to still further increase our sense of vision.

[1] Discourse delivered at the Royal Institution on Friday, May 30, 1890, by Mr. A. A. Common.

I will ask you to bear with me when I mention some things that are very well known, but which if brought to mind may render the subject much more easy. Within pretty narrow limits the principles involved in the construction of the telescope are the same whatever form it ultimately assumes. I will take as an illustration the telescope before me, which has served for the finder to a large astronomical telescope, and of which it is really a model. On examination we find that it has, in common with all refracting telescopes, a large lens at one end and several smaller ones at the other; the number of these small lenses varies according to the purpose for which we use the telescope. Taking out this large lens we find that it is made of two pieces of glass; but as this has been done for a purpose to be presently explained which does not affect the principle, we will disregard this, and consider it only as a simple convex lens, to the more important properties of which I wish first of all particularly to draw your attention, leaving the construction of telescopes to be dealt with later on.

Stated shortly, such a lens has the power of refracting or bending the rays of light that fall upon it: after they have passed through the lens the course they take is altered; if we allow the light from a star to fall upon the lens, the whole of the parallel rays coming from the star on to the front surface are brought by this bending action to a point at some constant distance behind, and can be seen as a point of light by placing there a flat screen of any kind that will intercept the light. For all distant objects the distance at which the crossing of the rays takes place is the same. It entirely depends on the substance of the lens and the curvature we give to the surfaces, and not at all upon the aperture or width of the lens. The brightness only of the picture of the star, depends upon the size of the lens, as that determines the amount of light it gathers together. If, instead of one star we have three or four stars together, we will find that this lens will deal with the light from each star just as it did with the light of the first one, and just in proportion to the distance they are apart in the sky, so will the pictures we see of them be apart on our screen. So if we let the light from the moon fall on our lens, all the light from the various parts of the moon's surface will act like the separate stars, and produce a picture of the whole moon (in the photographic camera the lens produces in this manner a picture of objects in front of it which we see on the ground glass). When we attempt to get pictures of near objects that do not send rays of light that are parallel we find that as the rays of light from them do not fall on the lens at the same angle to the axis the picture is formed further away from the lens. The nearer the object whose picture we wish to throw upon the screen is to the lens, the further the screen must be moved. If we try this experiment we will find, when we have the object at the same distance as the screen, the picture is then of the same size as the object, and the distance of the screen from the lens is twice that which we have found as the focal length; on bringing the object still nearer the lens, we find we must move the screen further and further away, until when the object is at the focus the picture is formed at an infinite distance away, or, what is more to our purpose, the rays of light from an object at the focus of a convex lens go away through the lens parallel, exactly as we have seen such parallel rays falling on the glass come to a focus, so that our diagram answers equally well whatever the direction of the rays; and this holds good in other cases where we take the effect of reflection as well as refraction.

We can also produce pictures by means of bright concave surfaces acting by reflection on the light falling upon them. Such a mirror or concave reflecting surface as I have here will behave exactly as the lens, excepting, of course, that it will form the picture in front instead of behind. The bending of the rays in the case of the convex lens is convergent, or towards the axis, for all parallel rays; if we use the reverse form of lens—that is, one thicker at the edge than in the middle—we find the reverse effect on the parallel rays; they will now be divergent, or bend away from the axis; and so with reflecting surfaces if we make the concavity of our mirror less and less, till it ceases and we have a plane, we will get no effect on the parallel rays of light except a change of direction after reflection. If we go beyond this and make the surface convex we then will have practically the same effect on the reflected rays as that given to the refracted ray by the concave glass lens.

As regards the size of the picture produced by lenses or mirrors of different focal length, the picture is larger just as the focal length is greater, and the angular dimension is converted into a linear one on the screen in due proportion. Now, as we

shall assume that the eye sees all things best at the distance of about nine inches, we may say that the picture taken with a lens of this focal length gives at once the proper and most natural representation we can possibly have of anything at which we can look. Such a picture of a landscape, if placed before the eye at the distance of nine inches, would exactly cover the real landscape point for point all over. A picture taken with a lens of shorter focal length, say four inches, will give a picture as true in all the details as the larger one, but if this picture is looked at, at nine inches distance, it is not a true representation of what we see; in order to make it so, we must look at it with a lens or magnifier. With a larger picture one can look at this at the proper distance, which always is the focal distance of the lens with which it was obtained, when we will see everything in the natural angular position that we have in the first case.

But if, instead of looking at this larger picture, which we may consider taken with a lens of say ninety inches focal length, at a distance of ninety inches, we look at it at a distance of nine inches, we have practically destroyed it as a picture by reducing the distance at which we are viewing it, and we have converted it into what is for that particular landscape a telescopic picture; we see it, not from the point at which it was taken, but just as if we were at one-tenth of the distance from the particular part that we examine. A telescope with a magnifying power of ten, would enable us to see the landscape just as we see it in the photograph, when we examine it in the way I have mentioned.

Having thus seen how a lens or mirror acts, we will turn our attention to the eye. Here we find an optical combination of lenses that act together in the same way as the single convex lens of which we have been speaking. We will call this combination the lens of the eye. It produces a picture of distant objects which in the normal eye falls exactly in focus upon the retina. We are conscious that we do see clearly at all distances beyond about nine inches.

At less than this distance objects become more and more indistinct as they are brought nearer to the eye. From what we have seen of the action of the lens in producing pictures of near and distant objects, we know that some movement of the screen must be made in order to get such pictures sharply focussed, a state of things necessary to perfect vision. We might therefore suppose that the eye did so operate by increasing when necessary the distance between the lens and retina, but we know that the same effect is produced in another way; in fact, the only other way. The eye by a marvellous provision of nature, secures the distinctness of the picture on the retina of all objects beyond a distance of about 9 inches, by slightly but sufficiently varying the curvature of one of the lenses; by an effort of will, we can make the accommodating power of the eye slightly greater, and so see things clearly a little nearer; but at about the distance of 9 inches, the normal eye is unconscious of any effort in thus accommodating itself to different distances. The picture produced by the lens of the eye whose focal length we will assume to be six-tenths of an inch falls on the retina, which we will assume further to be formed of a great number of separate sensible points, which, as it were, pick up the picture where it falls on these points, and through the nervous organization, produce the sense of vision. Possibly when these points are affected by light, there may be some connective action, either produced by some slight spherical aberration of the lens or otherwise; but I do not wish to go any further in this matter than is necessary to elucidate my subject. What I am concerned with now is the extent to which the sensibility of the retina extends. Experiment tells us that it extends to the perception of two separate points of light whose angular distance apart is one minute of arc, or in other words at the distance we can see best, two points whose distance apart is about 1/400 of an inch.

This marvellous power can be better appreciated when we remember that the actual linear distance apart of two such points on the retina is just a little more than 1/6000 of an inch.

In dealing with the shape of small objects the difference between a circle, square, and triangle, can be detected when the linear size of either is about 1/2000 of an inch. It may be therefore fairly taken that these separate sensible points of the retina are somewhere about 1/12,000 part of an inch apart from each other. Wonderfully minute as must this structure be, we must remember, as we have already shown, that the actual size of the image it deals with is also extremely small. This minuteness becomes apparent when we consider what occurs when we look at some well-known object, such as the full moon. Taking the angular diameter of the moon as 30 minutes of arc, and the focal length of the eye at six-tenths of an inch, we find the linear diameter of the picture of the full moon on the retina is about 1/200 of an inch, and assuming that our number of the points in the retina is correct, it follows that the moon is subject to the scrutiny of 2800 of these points, each capable of dealing with the portion of the picture that falls upon it.

That is to say, the picture, as the retina deals with it, is made up of this number of separate parts, and is incapable of further division, just as if it were a mosaic. I think this is really the case, and as such a supposition permits us to explain not only what occurs when we assist the eye by means of the telescope, but also what occurs when we use the telescope for photographing celestial objects, we will follow it up.

In the case of the eye we suppose the image of the moon to be made up through the agency of these 2800 points, each one capable of noting a variation in the light falling upon it. In order to make this rather important point plainer, I have had a diagrammatic drawing made on this plan. Taking a circle to represent the full moon, I have divided it into this number of spaces, and into each space I have put a black dot, large or small, according to the intensity of the light falling on that part of the image as determined by looking at a photograph of the moon. You will see by the picture of this moon the effect produced. It represents to those who are at a sufficient distance the moon much as it is really seen in the sky.

We can now with a lens of the same focal length as the eye obtain a picture of the full moon exactly of the size of the actual picture on the retina, and if we take a proper photographic process we can get particles of silver approximately of the same sizes as the dots we have used in making our diagram of the moon; the grouping is not exactly the same, but we may take it as precisely so for our purpose. I have not any photographs of the full moon of this size, but I have some here of the moon about five, seven, and eight days old, which give a good idea of what I mean by the arrangements of the particles of silver being like our diagram.

It is now quite apparent that if we can by any means increase the size of the picture of the moon on the retina or make it larger on the photographic plate, we would be able to employ more of our points or particles of silver, and so be able to see more clearly just in proportion as we increase the size of the picture in relation to the size of the separate parts that make it.

Now the telescope enables us to do this for the eye, and a longer focussed lens will give us a larger photographic picture.

Let us assume that by means of the telescope we have increased the power of the eye one hundred times. The picture of the moon on the retina would now be one-half inch diameter, and instead of employing 2800 points to determine its shape, and the various markings upon it, we should be employing 28,000,000 of these points; and similarly with the photograph, by increasing the size of our lens we will obtain a picture made up of this enormous number of particles of silver. But we can go further in the magnification of the picture on the retina—we can also use a still longer focus photographic lens.

A power of magnification of one thousand is quite possible under favourable circumstances; this means that the picture of one two-hundredth of an inch would be now of five inches in diameter, so we must deal with only a portion of it. Let us take a circle of one-tenth of this, equalling one-hundredth of our original picture, which in the eye, unaided by the telescope, would have a diameter of one two-thousandth of an inch, or an area of less than one five-millionth of a square inch. This means that with this magnification, we have increased the power so enormously that we are now employing for the photographic picture two thousand eight hundred million particles of silver, and in the eye the same degree of increase in the number of points of the retina employed in scrutinizing the picture piece by piece as successive portions are brought into the central part.

Photography enables me to show that the result I have given of the wonderful effect of increasing the optical power is perfectly correct as far as it is concerned. We will deal with a part only of the moon, representing, as I have just said, about one-tenth of its diameter, or one-hundredth of its visible surface. Two such portions of the moon are marked, as you see, on the diagram. I have selected these portions as I am able to show you them just as taken on a large scale by photography so that you can make the comparison in the most certain manner;

but let us first analyze our diagrammatic moon—let us magnify it about ten times, and see what it looks like.

I now show you a picture of this part of the diagram, inclosing the portions I wish to speak about, magnified ten times, so that you can see that about twenty-eight of our points, and by supposition twenty-eight of our particles of silver on the photographic plate, make up the picture. You will see that these dots vary in size; the difference is due to the amount of light falling within what we may call the sphere of action of each point, and should represent it exactly. The result can hardly be called a picture, as it conveys no impression of continuity of form to the mind. We have got down to the structure or separate parts, and to the limit of the powers of the eye and the photographic plate, of course on the assumption we have made as to the size of the points in the one case and the particles of silver in the other. I will now show you the same parts of the moon as represented by the circles on our diagram exactly as delineated by photography. You now see a beautiful picture giving mountains, valleys, craters, peaks, and plains, and all that makes up a picture of lunar scenery. We have thus seen how the power of the eye is increased by the enlargement of the picture on the retina by the telescope, and also how, by increasing the size of the photograph, we also get more and more detail in the picture.
